#### Abstract

\section*{Algorithms for NP-hard Optimization Problems and Cluster Analysis by <br> Nan Li}

The set cover problem, weighted set cover problem, minimum dominating set problem and minimum weighted dominating set problem are all classical NP-hard optimization problems of great importance in both theory and real applications. Since the exact algorithms, which require exhaustive exploration of exponentially many options, are infeasible in practice, approximation algorithms and heuristic algorithms are widely used to find reasonably good solutions in polynomial time. I propose novel algorithms for these four problems. My algorithms for the weighted set cover and minimum weighted dominating set problems are based on a three-step strategy. For the weighted set cover problem, in the first step, we reserve the sets indispensable for the optimal solution and reduce the problem size. In the second step, we build a robust solution with a novel greedy heuristic. Sets are iteratively selected according to a measure which integrates the weight, the coverage gain for the current iteration and the global coverage capacity of each set. It favors the sets that have smaller weights and better extend or consolidate the coverage, especially on the items that are contained in less sets. Since the obtained solution tends to have a robust coverage, in the third step, we further improve it by removing the redundant sets in an efficient way. For the minimum weighted dominating set problem, we first reserve the indispensable vertices for the optimal solution. Then we convert it into a weighted set cover problem to solve it. These two algorithms can be used to solve the set cover problem and minimum dominating set problem by simply considering all the sets or vertices as having the same weights. Extensive experimental evaluations on a large number of synthetic and real-world set cover instances and graphs from many domains demonstrate the
superiority of my algorithms over state-of-the-art.
Cluster analysis is a fundamental problem in data analysis, and has extensive applications in artificial intelligence, statistics and even in social sciences. The goal is to partition the data objects into a set of groups (clusters) such that objects in the same group are similar, while objects in different groups are dissimilar.

Most of the existing algorithms for clustering are designed to handle data with only one type of attributes, e.g. continuous, categorical or ordinal. Mixed data clustering has received relatively less attention, despite the fact that data with mixed types of attributes are common in real applications. I propose a novel affinity learning based framework for mixed data clustering, which includes: how to process data with mixed-type attributes, how to learn affinities between data points, and how to exploit the learned affinities for clustering. In the proposed framework, each original data attribute is represented with several abstract objects defined according to the specific data type and values. Each attribute value is transformed into the initial affinities between the data point and the abstract objects of attribute. I refine these affinities and infer the unknown affinities between data points by taking into account the interconnections among the attribute values of all data points. The inferred affinities between data points can be exploited for clustering. Alternatively, the refined affinities between data points and the abstract objects of attributes can be transformed into new data features for clustering. Experimental results on many real world data sets demonstrate that the proposed framework is effective for mixed data clustering. This work was published in our IJCAI 2017 paper Li \& Latecki (2017).

Clustering aggregation, also known as consensus clustering or clustering ensemble, aims to find a single superior clustering from a number of input clusterings obtained by different algorithms with different parameters. I formulate clustering aggregation as a special instance of the maximum-weight independent set (MWIS) problem. For a given data set, an attributed graph is constructed from the union of the input cluster-
ings. The vertices, which represent the distinct clusters, are weighted by an internal index measuring both cohesion and separation. The edges connect the vertices whose corresponding clusters overlap. Intuitively, an optimal aggregated clustering can be obtained by selecting an optimal subset of non-overlapping clusters partitioning the data set together. I formalize this intuition as the MWIS problem on the attributed graph, i.e., finding the heaviest subset of mutually non-adjacent vertices. This MWIS problem exhibits a special structure. Since the clusters of each input clustering form a partition of the dataset, the vertices corresponding to each clustering form a maximal independent set (MIS) in the attributed graph. I propose a variant of simulated annealing method that takes advantage of this special structure. My algorithm starts from each MIS, which is close to a distinct local optimum of the MWIS problem, and utilizes a local search heuristic to explore its neighborhood in order to find the MWIS. Extensive experiments on many challenging data sets show that both my algorithm for the maximum-weight independent set problem and my approach to the application of clustering aggregation achieve good performance. This work was published in our NIPS 2012 paper Li \& Latecki (2012). Some new results were published in our IJCAI 2017 paper Fan et al. (2017).

## ACKNOWLEDGEMENTS

I would like to express my heartfelt gratitude to my advisor, Dr. Longin Jan Latecki. He has always been supportive and patient. Without his guidance and encouragement, none of my research works would have been possible.

I would also like to thank the other members in my dissertation committee, Dr. Haibin Ling, Dr. Slobodan Vucetic, and Dr. Yimin Zhang, for their insightful comments and encouragement.

The discussions with other group members, Zhuo Deng, David Dobor, Meng Yi, Tianyang Ma, Le Shu, Chen Shen, Ren-Hau Howard Liu and Cong Rao have always been inspiring. I've learned a lot from them. I'm very grateful for that.

Last but not the least, I would like to thank my wife and my parents for their love and support.

To My Wife - Pei Qiu, and My Parents

## CHAPTER 1

## Algorithms for Weighted Set Cover and Minimum Weighted Dominating Set Problems

### 1.1 Introduction

Given a set of items, called the universe $U$, and a collection $\mathcal{F}$ of sets whose union equals $U$, the set cover problem is to find the smallest sub-collection of $\mathcal{F}$ whose union equals the universe $U$. The weighted set cover problem, in which each set is associated with a positive weight, is to find the sub-collection of $\mathcal{F}$ whose union equals $U$ with the minimum sum of weights.

Given an undirected graph $G=(V, E)$, a dominating set is a subset $D \subseteq V$ such that for every vertex $v \in V$, either $v \in D$ or at least one neighbor of $v$ is in $D$. The minimum dominating set problem is to find a dominating set of the minimum size. If each vertex is associated with a positive weight, the minimum weighted dominating set problem is to find a dominating set for which the sum of weights is minimized.

The set cover and minimum dominating set problems are both classical NP-hard problems of great importance in theory. They are equivalent under L-reductions Kann (1992). It means given an instance of one problem, we can construct an equivalent instance of the other problem. Therefore, algorithms for one problem can be applied to the other problem with minor modifications. The weighted set cover and minimum dominating set problems are also closely related NP-hard problems.

The unweighted and weighted set cover and minimum dominating set problems arise in a great number of applications, including artificial intelligence Reiter (1987);

Zhao \& Ouyang (2007); Saha \& Getoor (2009); Shen \& Li (2010); Yao \& Fei-Fei (2012); Cao \& Snavely (2013); Magri \& Fusiello (2016), operations research Caprara et al. (1999), computer networking Stojmenovic et al. (2002); El Houmaidi \& Bassiouni (2003); Subhadrabandhu et al. (2004); Aoun et al. (2006); Samuel et al. (2009), web technology Cooper et al. (2005); Wu et al. (2006); Stergiou \& Tsioutsiouliklis (2015), social networks Kelleher \& Cozzens (1988); Eubank et al. (2004); F. Wang et al. (2011), bioinformatics Nacher \& Akutsu (2016), planning Mihail (1999), database Sellis (1988); Golab et al. (2008) and so on.

However, since these problems are all NP-hard, the exact algorithms, which require exhaustive exploration of exponentially many options, are infeasible in practice. Approximation algorithms, which are able to find reasonably good solutions in polynomial time, are widely used to solve these problems in real applications.

The classic greedy algorithm for the set cover problem repeatedly picks a set that contains the largest number of uncovered items until all the items in the universe are covered. This simple greedy heuristic achieves an approximation ratio of $\ln \delta+1$, where $\delta=\max \{|S|: S \in \mathcal{F}\}$ is the maximum cardinality of the sets in $\mathcal{F}$. In fact, no algorithm can guarantee to improve this approximation ratio by much Feige (1998). Moreover, it has been observed that this algorithm is very effective in practice, especially when compared to other approximation algorithms Grossman \& Wool (1997); Gomes et al. (2006). It often finds only a small percentage $(<10 \%)$ more sets than the optimal solution. The standard greedy algorithm for the minimum dominating set problem is based on the same heuristic. It repeatedly picks a vertex which covers the maximum number of previously uncovered vertices until a dominating set is obtained. Its approximation ratio is $\ln \delta^{\prime}+2$, where $\delta^{\prime}$ is the maximum degree of $G$. For the weighted set cover problem, the classic greedy algorithm iteratively selects a set by the number of uncovered items it contains per unit weight or the inverse. It achieves an approximation ratio of $\ln |U|+1$, where $|U|$ is the cardinality of universe
$U$. The standard greedy algorithm for the minimum weighted dominating set problem is based on the same heuristic and achieves an approximation ratio of $\ln |V|+1$ on graph $G=(V, E)$.

Besides the standard algorithms described above, there are many other approximation algorithms based on greedy heuristics for the weighted or unweighted set cover and minimum dominating set problems. Sanchis (2002) described four different approximation algorithms for the minimum dominating set problem and performed extensive experimental evaluations to compare them with the standard algorithm. Ablanedo-Rosas \& Rego (2010) introduced a number of normalization rules to generate surrogate constraints for the weighted set cover problem. Although it's impossible to prove the approximation ratios for these algorithms, experimental evaluations showed that their performance was usually better than those of the standard greedy algorithms. Some other algorithms Cormode et al. (2010); Stergiou \& Tsioutsiouliklis (2015); Eubank et al. (2004); Campan et al. (2015) are designed with the focus on efficiency. With more or less sacrifice on the performance, these algorithms can significantly reduce the processing time, especially for large instances.

In recent years, a great number of local search based approximation algorithms were proposed for the weighted or unweighted set cover problem Yagiura et al. (2006); Kinney et al. (2007); Caserta (2007); Lan et al. (2007); Bautista \& Pereira (2007); Sundar \& Singh (2012); Crawford et al. (2014); Mulati \& Constantino (2011); Ren et al. (2010); Beasley \& Chu (1996); Naji-Azimi et al. (2010); Y. Wang, Ouyang, et al. (2017), minimum weighted or unweighted dominating set problem Raka et al. (2010); Potluri \& Singh (2013); Nitash \& Singh (2014); Chaurasia \& Singh (2015); Bouamama \& Blum (2016); Y. Wang, Cai, \& Yin (2017); Hedar \& Ismail (2012, 2010); Ho et al. (2006). These algorithms usually achieve good results on small or medium sparse instances. However, they are still too complex to process medium dense or large instances. In fact, within a reasonable amount of time, most of them
cannot achieve better results than some of the greedy approximation algorithms on medium dense or large instances.

I propose novel algorithms for the weighted set cover and minimum weighted dominating set problems.

The proposed algorithms are based on a three-step strategy. For the weighted set cover problem, in the first step, we reserve the sets indispensable for the optimal solution. A set is defined as indispensable if it covers at least one item on its own. Then we remove the items covered by the reserved sets and the sets whose items are all covered (include but not limited to the reserved sets) to get a smaller set cover instance. In the second step, we build a robust solution with a novel greedy heuristic. Specifically, we seek the set covering by iteratively selecting a set according to a measure which integrates the related weights, the coverage gain for the current iteration and the global coverage capacity of each set. It favors the sets that have smaller weights and better extend or consolidate the coverage, especially on the items that are contained in less sets. Since the obtained solution tends to have a robust coverage, in the third step, we further improve it by removing the redundant sets in an efficient way. The remaining sets and those reserved in the first step together constitute the final approximate solution.

For the minimum weighted dominating set problem, we reserve the indispensable vertices in the first step. A vertex is defined as indispensable if it is isolated or adjacent to at least one vertex of degree exactly one. Then we convert it into a weighted set cover problem by considering the vertex set $V$ as the universe $U$, and $\mathcal{F}=\left\{S_{1}, S_{2}, \ldots, S_{n}\right\}$ where set $S_{v}$, with the same weight as vertex $v$, consists of $v$ and all its adjacent vertices in $G$, as the set family. The items covered by the sets corresponding to the reserved vertices and the sets whose items are all covered are removed. We then solve the reduced weighted set cover problem. The vertices corresponding to the sets of the final set covering and the vertices reserved in the first
step constitute the final dominating set.
Extensive experimental evaluations on a large number of synthetic and real world instances from many domains demonstrate the superiority of my algorithms over state-of-the-art.

### 1.2 Related Work

The classic greedy algorithm for set cover problem is due to Johnson (1974); Lovász (1975); Chvatal (1979). It repeatedly picks the set that contains the largest number of uncovered items until all items in the universe are covered. The same heuristic is then applied to the minimum dominating set problem, because the two problems are equivalent under L-reductions.

Ablanedo-Rosas \& Rego (2010) introduced a number of normalization rules to improve the classic greedy algorithm for the weighted set cover problem, which iteratively selects a set by the number of uncovered items it contains per unit weight or the inverse. The essential idea of these rules is to take into account the number of sets each item is contained in when computing the coverage gain of each set, instead of simply using the number of uncovered items it contains. For example, Rule $A$ assigns each item a weight which is defined as the inverse of the number of sets containing it. The coverage gain of each set is defined as the sum of such weights of the uncovered items it contains. The rest rules introduced in Ablanedo-Rosas \& Rego (2010) are simple variants of Rule $A$. Experimental evaluations demonstrate the effectiveness of these normalization rules, especially when solving large scale and real-world instances. However, some of these rules, such as the "Adjusted" versions and Rule C, not only lack theoretical justifications, but also make very little difference on performance in comparison to the other rules.

Cormode et al. (2010) proposed an efficient set cover algorithm for processing very large data sets, especially those resident on disk. All the sets are first partitioned into
sub-collections based on their sizes. Then starting from the sub-collection with the largest sets, each set is iteratively processed. In each iteration, if the set contains more uncovered items than the size threshold of current sub-collection, it is selected and its uncovered items are covered. Otherwise, the set is moved to the appropriate sub-collection.

Most practical approximation algorithms for the minimum weighted dominating set problem on general graphs are based on the local search techniques. Among them, the $C C^{2} F S$ algorithm proposed in Y. Wang, Cai, \& Yin (2017) is probably the best one in terms of both performance and efficiency. $C C^{2} F S$ is based on two new ideas. The first idea is a new variant of the Configuration Checking Cai et al. (2011) strategy, which has been widely applied to many combinatorial optimization problems in order to reduce the cycling phenomenon in local search. The new variant defines the configuration of a vertex $v$ to be its two-level neighborhood, which is the union of the neighborhood $N(v)$ and the neighborhood of each vertex in $N(v)$. The second idea is a frequency based scoring function for vertices, according to which the score of each vertex is calculated. Another state-of-the-art local search algorithm is ACO-PP$L S$ proposed in Potluri \& Singh (2013). It uses an ant colony optimization method by considering the pheromone deposit on the node and a preprocessing step immediately after pheromone initialization. Both $C C^{2} F S$ and $A C O-P P-L S$ can achieve good results on small or medium graphs. However, as the other local search algorithms, they are still too complex to process large graphs.

For solving the minimum dominating set problem, Sanchis (2002) described five different approximation algorithms and performed extensive experimental analyses on them. The first algorithm, "Greedy", is the well-known and standard approximation algorithm. It starts with an empty set $D$ and iteratively adds a vertex to $D$ which covers the maximum number of previously uncovered vertices. The second algorithm, "Greedy_Rev", works in the opposite way. Initially, $D$ contains every vertex in the
graph. At each iteration, the vertex, which is of the smallest degree and does not uniquely cover any vertex, is removed from $D$. The third algorithm, "Greedy_Ran", is similar to the "Greedy" algorithm, with the only difference being that in each iteration it selects the vertex to be added probabilistically according to the number of additional vertices it would cover. The fourth algorithm, "Greedy_Vote", defines a measure "vote" for each vertex $v$ as $\operatorname{vote}(v)=1 /(1+\operatorname{degree}(v))$. At each iteration, instead of selecting the vertex which covers the maximum number of uncovered vertices as the "Greedy" algorithm does, it selects the vertex which is of the maximum sum of votes from the uncovered vertices. The fifth algorithm, "Greedy_Vote_Gr", performs an exhaustive search after running "Greedy_Vote" to determine whether it is possible to remove any two vertices from $D$, and replace them with either one or no vertices, while still retaining a dominating set. Experimental evaluations on many small synthetic graphs demonstrate that, in comparison to the standard "Greedy" algorithm, "Greedy_Vote" exhibits superiority on some graphs, while "Greedy_Ran" and "Greedy_Rev" are found not to be worthwhile. The exhaustive local search step of "Greedy_Vote_Gr" is very time-consuming and the improvements on results are limited. Eubank et al. (2004) proposed a "FastGreedy" heuristic for determining the minimum dominating set in the context of studying the algorithmic and structural properties of very large realistic social contact networks. It also defined a "VRegularGreedy" approximation algorithm, which adds the location neighbors of the people vertices of degree one into the dominating set before applying the standard greedy algorithm. Campan et al. (2015) introduced two efficient approximation algorithms for the minimum dominating set problem. The first algorithm attempts to improve the running time of the standard greedy algorithm by removing all the covered vertices from the remaining graph in each iteration. The second algorithm first adds neighbors of the vertices of degree one into the dominating set. After removing all the covered vertices, the first algorithm is applied to the remaining graph. There
are a few works searching for the minimum dominating set based on meta-heuristics, such as simulated annealing Hedar \& Ismail (2012), genetic algorithm Hedar \& Ismail (2010) and ant colony optimization Ho et al. (2006). As a typical example, Hedar \& Ismail (2012) proposed a simulated annealing based local search algorithm for solving the minimum dominating set problem. At each step, depending on whether the current solution is a dominating set, a trial solution is generated by removing, adding or replacing a vertex in a probabilistic manner according to the degree of vertices. Simulated annealing technique is used to avoid entrapments in poor local optima.

### 1.3 Our Work

In this section, I present my three-step framework of approximation algorithms for the weighted set cover and the minimum weighted dominating set problems.

### 1.3.1 Weighted Set Cover Problem

Given the item universe $U=\left\{i_{1}, i_{2}, \ldots, i_{m}\right\}$, the set family $\mathcal{F}=\left\{S_{1}, S_{2}, \ldots, S_{n}\right\}$ whose union equals $U$ and the positive weight $w(S)$ on each set $S$, we aim to find the sub-collection of $\mathcal{F}$ whose union equals $U$ and the sum of set weights is minimized.

In the first step, we identify every set in $\mathcal{F}$ which covers at least one item in $U$ on its own. Obviously, these sets are indispensable for the optimal set covering. Let $\mathcal{F}_{R}$ denote the set of these indispensable sets. We remove the items covered by the sets in $\mathcal{F}_{R}$. Let $U^{\prime}$ denote the remaining uncovered items. Then we remove the empty sets, which do not contain any items in $U^{\prime}$. Let $\mathcal{F}^{\prime}$ denote the remaining sets. Obviously, $\mathcal{F}_{R} \subseteq \mathcal{F} \backslash \mathcal{F}^{\prime}$. Now we have a smaller weighted set cover problem: to find the sub-collection of $\mathcal{F}^{\prime}$ whose union equals the universe $U^{\prime}$ and the sum of set weights is minimized.

In the second step, we start with an empty set $\mathcal{F}^{\prime}{ }_{C}=\emptyset$ and iteratively select a set from $\mathcal{F}^{\prime}$ into $\mathcal{F}_{C}^{\prime}$ until the union of sets in $\mathcal{F}^{\prime}{ }_{C}$ equals $U^{\prime}$.

Let $w i(S)$ denote the inverse of weight $w(S)$ of set $S$. That is,

$$
\begin{equation*}
w i(S)=\frac{1}{w(S)} \tag{1.3-1}
\end{equation*}
$$

For each item $i$, we compute the sum of weight inverses of the sets containing $i$

$$
\begin{equation*}
S I W_{i}=\sum_{S \in C_{i}} w i(S) \tag{1.3-2}
\end{equation*}
$$

where $C_{i}$ denotes the set of sets in $\mathcal{F}^{\prime}$ which contain item $i$.
Then for each set $S$ in $\mathcal{F}^{\prime}$, we define its local coverage efficiency on each item $i \in S$ as

$$
\begin{equation*}
L C E_{S, i}=\frac{w i(S)}{S I W_{i}} \tag{1.3-3}
\end{equation*}
$$

Obviously, $L C E$ is in range $(0,1]$
Based on the local coverage efficiencies, we define the global coverage capacity of each set $S$ as

$$
\begin{equation*}
G C C_{S}=\sum_{i \in S}\left(L C E_{S, i}\right)^{\beta_{g}} \tag{1.3-4}
\end{equation*}
$$

where $\beta_{g} \in[0,+\infty)$ is a parameter for adjusting the difference of local coverage efficiencies. $\beta_{g}>1$ increases the relative weight of larger $L C E$, while $\beta_{g}<1$ works in the opposite way.

We define the local coverage gain of each set $S$ in each iteration as

$$
\begin{equation*}
L C G_{S}=\sum_{i \in S \cap U_{u}^{\prime}}\left(L C E_{S, i}\right)^{\beta_{l}} \tag{1.3-5}
\end{equation*}
$$

where $U_{u}^{\prime}$ denotes the set of uncovered items as of the current iteration, the parameter $\beta_{l} \in[0,+\infty)$ is similar to $\beta_{g}$ for adjusting the difference of local coverage efficiencies. Based on the local coverage gain and global coverage capacity, we define the

measure of coverage benefit for each set $S$ as

$$
\begin{equation*}
C B_{S}=L C G_{S}+\gamma \times G C C_{S} \tag{1.3-6}
\end{equation*}
$$

where the parameter $\gamma \in[0,+\infty)$ is for adjusting the relative weight of $G C C$.
We iteratively select sets according to their coverage benefits. Specifically, in each iteration, we select the set $S^{*}$ which has the maximum coverage benefit (with ties broken randomly) and covers at least one uncovered item.

$$
\begin{equation*}
S^{*}=\operatorname{argmax}_{S} C B_{S} \quad \text { s.t. }\left|S \cap U_{u}^{\prime}\right|>0 \tag{1.3-7}
\end{equation*}
$$

Obviously, this greedy heuristic favors the sets that have smaller weights and better extend or consolidate the coverage, especially on the items that are contained in less sets. Its specific effects are illustrated in Figure 1.1.

Figure 1.1 shows a state during the iterative process of solving a weighted set cover problem, in which $|\mathcal{F}|>10$ and $|U|>8$. Suppose the first 10 sets $S_{1}$ to $S_{10}$ only contain some of the first 8 items, i.e. $i_{1}$ to $i_{8} . S_{10}$, which is marked in gray, is already selected, while $S_{1}$ to $S_{9}$ are not. The 8 items are only contained in
some of these 10 sets. $i_{7}$ and $i_{8}$, which are marked in gray, are already covered by $S_{10}$, while $i_{1}$ to $i_{6}$ are not covered yet. A cell $(S, i)$ is empty if the set $S$ does not contain the item $i$. Otherwise, $S$ contains $i$ and cell $(S, i)$ shows the set weight $w(S)$. Suppose $\beta_{l}=1, \beta_{g}=1, \gamma=1$, we calculate $S I W, L C G, G C C$ and $C B$ for our greedy heuristic. In addition, we calculate the measures for selecting sets according to the classic greedy heuristic and the Rule $A$ proposed in Ablanedo-Rosas \& Rego (2010). The other rules proposed in Ablanedo-Rosas \& Rego (2010), i.e. Rule B to Rule I, have essentially the same effects as Rule $A$.

The classic greedy heuristic selects the set with the maximum number of uncovered items per unit weight $(I W)$ or the minimum of its inverse. The $I W$ is defined as

$$
\begin{equation*}
I W_{S}=\frac{\left|S \cap U_{u}^{\prime}\right|}{w(S)} \tag{1.3-8}
\end{equation*}
$$

where $U_{u}^{\prime}$ denotes the set of uncovered items as of the current iteration.
Let $R A$ denote the measure derived from Rule $A$. It is defined as

$$
\begin{equation*}
R A_{S}=\frac{w(S)}{\sum_{i \in S \cap U_{u}^{\prime}} \frac{1}{\left|C_{i}\right|}} \tag{1.3-9}
\end{equation*}
$$

where $C_{i}$ denotes the set of sets which contain item $i$.
In Ablanedo-Rosas \& Rego (2010), Rule $A$ selects the set with the minimum $R A$. We implement Rule $A$ to select the set with the maximum $R A^{\prime}=1 / R A$ for consistency.

Figure 1.1 illustrates five intuitive rules for selecting sets. (1) $S_{1}$ and $S_{2}$ contain the same uncovered item $i_{1}$ and $w\left(S_{1}\right)<w\left(S_{2}\right)$. Apparently, between them, $S_{1}$ should be selected. We call this Rule 1. The three measures $C B, I W$ and $R A^{\prime}$ all implement Rule 1. (2) $S_{1}$ and $S_{3}$ each contains 1 uncovered item and both have the same weights. Besides $S_{1}$, selecting $S_{2}$ can cover the item $i_{1}$. Similarly, besides $S_{3}$, selecting $S_{9}$ can cover $i_{2}$. Since $w\left(S_{2}\right)<w\left(S_{9}\right)$, between $S_{1}$ and $S_{3}$, intuitively, we

Table 1.1: Relationships between measures and rules

|  | Rule 1 | Rule 2 | Rule 3 | Rule 4 | Rule 5 |
| :--- | :---: | :---: | :---: | :---: | :---: |
| $C B$ | $\checkmark$ | $\checkmark$ | $\checkmark$ | $\checkmark$ | $\checkmark$ |
| $I W$ | $\checkmark$ |  |  | $\checkmark$ |  |
| $R A^{\prime}$ | $\checkmark$ |  | $\checkmark$ | $\checkmark$ |  |

should favor $S_{3}$. Otherwise, it is more risky that $S_{9}$ may be selected to cover $i_{2}$ later. We call this Rule 2. Obviously, only the measure $C B$ implements Rule 2. (3) $S_{1}$ and $S_{4}$ each contain 1 uncovered item and both have the same weights. Unlike $S_{9}$ on $i_{2}$, there are no sets that contain $i_{3}$ and have larger weights than the sets containing $i_{1}$. Apparently, Rule 2 does not apply here. However, in comparison to $i_{1}$, there are more sets containing $i_{3}$. Intuitively, $i_{3}$ is easier to be covered. Therefore, we should favor $S_{1}$ over $S_{4}$ this time, because $S_{1}$ covers a more "difficult" item. We call this Rule 3 . Both $C B$ and $R A^{\prime}$ implement Rule 3. (4) $S_{1}$ and $S_{5}$ have the same weights. But, since $S_{5}$ contains 2 uncovered items, while $S_{1}$ only contains 1 , it is straightforward for us to choose $S_{5}$. We call this Rule 4. $C B, I W$ and $R A^{\prime}$ all implement Rule 4. (5) $S_{1}$ and $S_{6}$ have the same weights. $S_{1}$ contains 1 uncovered item $i_{1}$, while $S_{6}$ also contains 1 uncovered item $i_{6}$. Moreover, $i_{1}$ and $i_{6}$ are both contained in 2 sets and the set weight patterns are exactly the same. However, $S_{6}$ contains 2 covered items, i.e. $i_{7}$ and $i_{8}$. Although selecting $S_{6}$ does not bring more coverage than selecting $S_{1}$, it can consolidate the existing coverage on $i_{7}$ and $i_{8}$. It is possible that such consolidations will help release some previously selected sets. Therefore, we favor $S_{6}$ over $S_{1}$ this time. We call this Rule 5 . Obviously, only the measure $C B$ implements Rule 5 .

The relationships between the three measures $C B, I W$ and $R A^{\prime}$, and the five rules are summarized in Table 1.1. Our measure $C B$ implements all the five rules, while $I W$ and $R A^{\prime}$ implement only 2 and 3 rules respectively. The individual effect of these abstract rules may not affect the final result in the simple example above, but combining their effects together can make a difference when solving the real problems.

With the proposed greedy heuristic, the obtained set covering tends to be robust,
which means each item is likely to be covered by more sets. Therefore, it has potential to be further improved.

In the third step, we remove the redundant sets in an efficient way. Specifically, we first identify every set in $\mathcal{F}^{\prime} C$ which covers at least one item in $U^{\prime}$ on its own. The other sets are considered to be potentially redundant and removed from $\mathcal{F}^{\prime}$. If the remaining sets in $\mathcal{F}^{\prime}{ }_{C}$ do not cover the entire $U^{\prime}$ any more, we iteratively select a set with the maximum number of uncovered items per unit weight, i.e. $I W$, from those potentially redundant sets and add it back to $\mathcal{F}^{\prime}{ }_{C}$, until the union of sets in $\mathcal{F}^{\prime}{ }_{C}$ equals to $U^{\prime}$. Finally, the sets in $\mathcal{F}^{\prime} C$ and those reserved in $\mathcal{F}_{R}$ together constitute the final solution.

$$
\begin{equation*}
\mathcal{F}^{*}=\mathcal{F}_{C}^{\prime} \cup \mathcal{F}_{R} \tag{1.3-10}
\end{equation*}
$$

### 1.3.2 Minimum Weighted Dominating Set

Given an undirected, vertex-weighted graph $G=(V, E, w)$, where $V$ is the set of vertices, $E$ is the set of edges, and $w: V \rightarrow \mathbb{R}^{+}$is a function that associates a positive weight $w(v)$ to each vertex $v \in V$, we aim to find a subset $D \subseteq V$ of vertices such that each vertex $v \in V$ is either in $D$ or has at least one neighbor in $D$, and the sum of weights is minimized.

In the first step, we identify and reserve a subset $V_{R} \subseteq V$ of vertices indispensable for the optimal solution. If $G$ contains isolated vertices with degree zero, obviously, these vertices should belong to $V_{R}$. In addition, we find all vertices with degree one. Each such vertex $v$ has only one direct neighbor $u$. If $w(v) \geq w(u), u$ should be added into $V_{R}$. Otherwise, $v$ itself must be added into $V_{R}$. If so, in the end, we can get a better dominating set with smaller or equal weight by simply replacing $v$ with $u$. Note that if $u$ is also with degree one and $w(v)=w(u)$, we need to make sure only one of $v$ and $u$ is added into $V_{R}$. By considering the vertex set $V$ as the universe $U$, and
$\mathcal{F}=\left\{S_{1}, S_{2}, \ldots, S_{|V|}\right\}$, where set $S_{v}$ consists of the vertex $v$ and all its adjacent vertices in $G$, as the set family, and $w^{\prime}\left(S_{v}\right)=w(v)$ as the set weight function, we convert the minimum weighted dominating set problem into a weighted set cover problem. Let $\mathcal{F}_{R}$ denote the sets corresponding to the reserved vertices in $V_{R}$. We follow the same procedures as in our set cover algorithm to reduce the obtained weighted set cover problem and then solve it. In the end, the vertices corresponding to the sets in the final $\mathcal{F}^{\prime}{ }_{C}$ and the vertices reserved in $V_{R}$ together constitute the approximate solution to the minimum weighted dominating set problem.

### 1.3.3 Theoretic Analysis

Our algorithm for the weighted set cover problem first reserves the sets indispensable for the optimal solution, and then reduces the problem size by removing the items covered by the reserved sets and the sets that do not contain any of the remaining items. This step can be finished in $\mathcal{O}(|\mathcal{F}||U|)$, where $|\mathcal{F}|$ is the set number and $|U|$ is the item number. For sparse set cover instances, it can significantly reduce the time consumed in the subsequent procedures. In the second step, we iteratively select sets according to their coverage benefits. The related values, including $L C E$, $G C C$ and $L C E^{\beta_{l}}$ can be calculated in $\mathcal{O}\left(\left|\mathcal{F}^{\prime}\right|\left|U^{\prime}\right|\right)$ before the iterative procedure. Therefore, the complexity of each iteration of our algorithm is the same as that of the classic greedy algorithm. However, since our algorithm does not pursue the coverage on items directly as the classic greedy algorithm does, it needs more iterations to reach the full coverage. In the third step, our algorithm first removes the potentially redundant sets from the obtained solution and then uses the same heuristic of the classic greedy algorithm to select sets from those removed to restore the full coverage. In the worst case, it is to run the classic greedy algorithm on the instance with sets in $\mathcal{F}^{\prime}{ }_{C}$ and items in $U^{\prime}$. However, since the number of potentially redundant sets is usually much smaller, this step is fast. The efficiency analysis on our minimum
weighted dominating set algorithm is similar.
It is very difficult to give the approximation ratios for our weighted set cover and minimum weighted dominating set algorithms. However, when applied to the unweighted set cover and minimum dominating set problems, the approximation ratios of our algorithms can be guaranteed in a simple way. Specifically, our algorithm for the unweighted set cover problem has three parameters: $\beta_{l}, \beta_{g}$ and $\gamma$. If we set $\beta_{l}=0$ and $\gamma=0$, it becomes a variant of the classic greedy approximation algorithm. The only difference is that this variant has a preprocessing and a post processing: the first step to reserve the indispensable sets and the third step to remove the redundant sets. Obviously, these two steps do not harm the final approximate solution. We know the approximation ratio of the classic greedy algorithm is $\ln \delta+1$, where $\delta=\max \{|S|: S \in \mathcal{F}\}$ is the maximum cardinality of sets in $\mathcal{F}$. Therefore, the approximation ratio of this variant is also $\ln \delta+1$. Since our algorithm can try any parameters and return the best result, as long as it tries $\beta_{l}=0$ and $\gamma=0$, we can guarantee the approximation ratio of $\ln \delta+1$. Similarly, our algorithm for the minimum dominating set problem can guarantee the approximation ratio of $\ln \delta^{\prime}+2$, where $\delta^{\prime}$ is the maximum degree of $G$.

### 1.4 Experimental Evaluation

We evaluate the performance of our algorithms on a large number of synthetic and real world instances from many domains. There are 4 groups of experiments on weighted set cover problem, set cover problem, minimum weighted dominating set problem and minimum dominating set problem.

In these experiments, the three parameters $\beta_{l}, \beta_{g}$ and $\gamma$ of our algorithms are varied with grid search. In order to give full play to our algorithms and also generate sufficient data for the subsequent analyses on parameters, we try a large number of parameter combinations. In Section 1.4.5, we give some guidelines for choosing values
of $\beta_{l}, \beta_{g}$ and $\gamma$.
Our algorithms and most of the comparison algorithms break ties randomly. The other comparison algorithms also have more or less random processing. Therefore, we run each experiment 10 times and report the average results. If we need to report the best or average results across different parameters, we first run 10 experiments with each distinct set of parameters and compute the average results. Then we select the best or compute the average across different parameters.

In each of the 4 groups of experiments, we compare our algorithm with the classic or standard greedy algorithm for that problem and its improved version that first reserves the indispensable sets or vertices. We name them $G r$ and $G r R$ uniformly in Sections 1.4.1, 1.4.2 1.4.3 and 1.4.4. It is easy to distinguish among them from the context.

Our algorithms and the comparison algorithms are all implemented in $\mathrm{C}++$. All the experiments are performed on a workstation with 4x AMD Opteron 61742.2 GHz processors and 64GB RAM.

### 1.4.1 Weighted Set Cover Problem

We evaluate the performance of our weighted set cover algorithm on 70 synthetic instances from the OR-Library Beasley (1990). The details of these test instances are summarized in Table 1.2. For example, the first instance "scp41" consists of 1000 sets and 200 items.

The optimal solutions of these instances are known. Their weights are given in the second columns of Table 1.3 and Table 1.4 . For example, the weight of the optimal solution of the first instance "scp41" is 429.

The three parameters $\beta_{l}, \beta_{g}$ and $\gamma$ of our algorithm are varied with grid search. Specifically, we have 320 combinations derived from $\beta_{l} \in\{0.5,0.75,1,1.25$, $1.5,2,3,4\} ; \beta_{g} \in\{0.5,0.75,1,1.25,1.5,2,3,4\} ; \gamma \in\{0,0.01,0.1,1,10\}$. However,

Table 1.2: Test Instances for Weighted Set Cover Problem

| scp64 | 1000 | 200 | scpe4 | 500 | 50 |  |  |  |
| scp65 | 1000 | 200 | scpe5 | 500 | 50 |  |  |  |

when $\gamma=0$, different $\beta_{g}$ make no difference. Therefore, there are a total of 264 really distinct combinations. The reason that we do not try $\beta_{l}<0.5$ or $\beta_{l}>4$, and $\beta_{g}<0.5$ or $\beta_{g}>4$, is because such extreme values minify or magnify the difference of set weights and the difference of set populations covering each item too much, which adversely affects the solution quality. We analyze the effects of $\beta_{l}, \beta_{g}$ and $\gamma$ in Section 1.4.5.

The comparison algorithms include the classic greedy algorithm $G r$ and its improved version $G r R$, which first reserves the indispensable sets, and the variants $G r R A, G r R B, G r R D$ and $G r R E$ based on the rules Rule $A$, Rule B, Rule D and Rule E introduced in Ablanedo-Rosas \& Rego (2010) respectively, which also first reserve the indispensable sets. We do not report the results of the other rules introduced in Ablanedo-Rosas \& Rego (2010), including Rule C, Rule F, Rule G, Rule H and Rule $I$, because, (1) according to our experiments, these rules make very little difference on performance in comparison to the other rules; and (2) these rules are simple variants of the other rules, but lack theoretical justifications.

The experimental results of weighted set cover problem are given in Table 1.3 and Table 1.4. Since the results of $G r$ and $G r R$ are identical on all the 70 instances, we only report those of $G r R$. Our results are the minimum sum of set weights of the

Table 1.3: Weighted Set Cover Results (Solution Weight), Part 1

solutions found by our algorithm with all distinct sets of parameters each averaged over 10 runs.

As we can see, our algorithm achieves significantly better results than the comparison algorithms. Our results across different sets of parameters are much better than those of the comparison algorithms on 65 instances and tie with those on the other 5 instances. Furthermore, on many instances, our results are equal to or very close to the optimal. This demonstrates the capability of our algorithm to find superior solutions.

### 1.4.2 Set Cover Problem

Our algorithm can solve the (unweighted) set cover problem by simply considering all sets as having the same weights, e.g. 1. We evaluate its performance on 8 real world unweighted instances from the Frequent Itemset Mining Dataset Repository 1 , which were used in Cormode et al. (2010). The details of these test instances are

[^0]Table 1.4: Weighted Set Cover Results (Solution Weight), Part 2

summarized in Table 1.5. For example, the first instance "chess" consists of 3196 sets and 75 items.

For our algorithm, different from the experiment on weighted set cover problem, we now also consider $\beta_{l}<0.5$ and $\beta_{g}<0.5$ for two reasons. First, there are no differences among set weights. The adverse effect of extreme values of $\beta_{l}$ and $\beta_{g}$, which is discussed in Section 1.4.1, is smaller. Second, as discussed in Section 1.3.3, by trying $\beta_{l}=0$ and $\gamma=0$, our algorithm can guarantee an approximation ratio. Therefore, we have 500 parameter combinations derived from $\beta_{l} \in\{0,0.25,0.5,0.75,1,1.25,1.5,2,3,4\} ; \beta_{g} \in\{0,0.25,0.5,0.75,1,1.25,1.5,2,3,4\} ;$ $\gamma \in\{0,0.01,0.1,1,10\}$. When $\gamma=0$, different $\beta_{g}$ make no difference. Therefore,

there are a total of 410 really distinct combinations.
The comparison algorithms include the classic greedy algorithm $G r$ for the set cover problem and its improved version $G r R$, which first reserves the indispensable sets, $G r R A, G r R B, G r R D$ and $G r R E$ based on the rules Rule $A$, Rule B, Rule D and Rule E Ablanedo-Rosas \& Rego (2010), which also first reserve the indispensable sets, and $D F G$ proposed in Cormode et al. (2010). $D F G$ algorithm has a parameter $p$, which governs both the theoretical approximation factor and running time. In Cormode et al. (2010), $p$ was set to be 1.001 and 1.05 when testing $D F G$ on the same 8 instances. For fair comparison, in addition to 1.001 and 1.05 , we vary $p$ with grid search in the range of $[1.005,1.1]$ with a step size of 0.005 , and report the best results.

As shown in Table 1.6, the performance of our algorithm is better than those of the comparison algorithms. Specifically, our algorithm achieves the best results on all the 8 instances. On chess, mushroom and accidents instances, which contain fewer items, some of the algorithms based on the normalization rules of Ablanedo-Rosas \& Rego (2010) can also achieve the best results. Their performance on the other instances are also very good in comparison to $G r, G r R$ and $D F G$.

### 1.4.3 Minimum Weighted Dominating Set Problem

We evaluate the performance of our algorithm for the minimum weighted dominating set problem on three benchmarks. The first one is the BHOSLIB benchmark ("mis" version) Xu et al. (2005), which consists of 41 graphs. The second one is the DIMACS complementary benchmark, which consists of 37 graphs. The third one

Table 1.7: BHOSLIB Benchmark ("mis" version)

consists of all the 139 undirected simple graphs in the Network Data Repository ${ }^{2}$ These real world graphs are from 12 different domains, including biological networks, collaboration networks, facebook networks, infrastructure networks, interaction networks, recommendation networks, retweet networks, scientific computing networks, social networks, technological networks, temporal networks and web link networks. The details of the graphs from BHOSLIB benchmark and DIMACS complementary benchmark are summarized in Table 1.7 and Table 1.8, while those of the graphs from Network Data Repository are given in Table A. 1 in Appendix A. For example, the first graph "frb30-15-1" in the BHOSLIB benchmark consists of 450 vertices and 17827 edges.

All these graphs are originally unweighted. We follow the method of Y. Wang, Cai, \& Yin (2017) to assign weights to the vertices. The weighting function is defined as $w\left(v_{k}\right)=(k \bmod 200)+1$, where $k$ is the vertex index.

In the experiments of minimum weighted dominating set problem, as in Section

[^1]1.4.1, we consider 320 parameter combinations derived from $\beta_{l} \in\{0.5,0.75,1$, $1.25,1.5,2,3,4\} ; \beta_{g} \in\{0.5,0.75,1,1.25,1.5,2,3,4\} ; \gamma \in\{0,0.01,0.1,1,10\}$. When $\gamma=0$, different $\beta_{g}$ make no difference. Therefore, there are a total of 264 really distinct combinations.

We compare our minimum weighted dominating set algorithm with the standard greedy algorithm $G r$ and its improved version $G r R$, which first reserves the indispensable vertices. Furthermore, in order to evaluate the quality of our results, we compare them to those of two state-of-the-art local search algorithms, $C C^{2} F S$ Y. Wang, Cai, \& Yin (2017) and $A C O-P P-L S$ Potluri \& Singh (2013). We are not able to obtain the source code of these two algorithms. However, since the settings of our experiments are the same as Y. Wang, Cai, \& Yin (2017), we can compare our results to those reported in Y. Wang, Cai, \& Yin (2017) directly. Note that in Y. Wang, Cai, \& Yin (2017), the "MIN" and "AVG" results are the minimal and average solution values of the 10 runs of experiment with different random seeds. Here our results correspond to the "AVG" results in Y. Wang, Cai, \& Yin (2017). On some graphs, there are no results reported in Y. Wang, Cai, \& Yin (2017). We mark them as "N/A". In the experiments of Y. Wang, Cai, \& Yin (2017), the time limit for $C C^{2} F S$ and $A C O$ $P P-L S$ was 1000 seconds. On some graphs, $A C O-P P-L S$ failed to find a dominating set within the time limit. The results were marked as "n/a". We keep these marks here.

The experimental results of minimum weighted dominating set problem are given in Table 1.9 and Table 1.10 in this section, and Table A.2 and Table A.3 in Appendix A. On BHOSLIB and DIMACS complementary benchmarks, since the results of $G r$ and $G r R$ are identical on all the graphs, we only report those of $G r R$. Our results are the minimum sum of vertex weights of the solutions found by our algorithm with all distinct sets of parameters each averaged over 10 runs.

As we can see, our results are significantly better than those of $G r R$. Moreover,

as an approximation algorithm based on greedy heuristic, our algorithm outperforms state-of-the-art local search based algorithms, which are much more complex and time-consuming. Specifically, our results are better than those of $A C O-P P-L S$ on most graphs. On the small or medium graphs, our results are very close to those of $C C^{2} F S$. On large graphs, our algorithm exhibits significant advantage over $C C^{2} F S$. Our algorithm's superiority on efficiency is evaluated in Section 1.4.5.

### 1.4.4 Minimum Dominating Set Problem

Our algorithm can solve the minimum (unweighted) dominating set problem by simply considering all vertices as having the same weights, e.g. 1. We evaluate its
performance on the 139 undirected simple graphs from the Network Data Repository.
In the experiments of minimum dominating set problem, as in Section 1.4.2, we consider 500 parameter combinations derived from $\beta_{l} \in\{0,0.25,0.5,0.75,1,1.25$, $1.5,2,3,4\} ; \beta_{g} \in\{0,0.25,0.5,0.75,1,1.25,1.5,2,3,4\} ; \gamma \in\{0,0.01,0.1,1,10\}$. When $\gamma=0$, different $\beta_{g}$ make no difference. Therefore, there are a total of 410 really distinct combinations.

The comparison algorithms include the standard greedy algorithm $G r$ and its improved version $G r R$ which first reserves the indispensable vertices, the two algorithms Alg. 3 and Alg. 4 proposed in Campan et al. (2015), the FastGreedy algorithm introduced in Eubank et al. (2004), the Greedy_Rev (Gr_Rev) and Greedy_Vote (Gr_Vote) algorithms described in Sanchis (2002), and the local search algorithm SAMDS proposed in Hedar \& Ismail (2012). We ignore the Greedy_Ran and Greedy_Vote_Gr algorithms described in Sanchis (2002), because according to both the experimental evaluations in Sanchis (2002) and our preliminary tests, the performance of Greedy_Ran is bad and instable, while the exhaustive local search step of "Greedy_Vote_Gr" is very time-consuming and the improvements over the Greedy_Vote algorithm are very limited. The FastGreedy algorithm is implemented based on the FastGreedy heuristic proposed in Eubank et al. (2004). It first sorts the vertices in descending order by their degrees, as $\left\{v_{1}, v_{2}, \ldots, v_{|V|}\right\}$ with $d\left(v_{1}\right) \geq d\left(v_{2}\right) \geq \ldots \geq d\left(v_{|V|}\right)$. Then the smallest index $i$ is picked such that $\left\{v_{1}, v_{2}, \ldots, v_{i}\right\}$ is a dominating set. The final dominating set excludes vertices $v_{j}$ which have $N\left[v_{j}\right] \subseteq \bigcup_{k<j} N\left[v_{k}\right]$, where $N[v]$ denotes vertex $v$ and its direct neighbors. $S A M D S$ Hedar \& Ismail (2012) is a local search algorithm based on the simulated annealing meta-heuristic. We follow the same strategy as in Hedar \& Ismail (2012) to set the initial temperature $T_{\max }$ to be large enough to make the initial probability of accepting transition close to 1 . In order to give full play to $S A M D S$, unlike in Hedar \& Ismail (2012), we do not set a fixed final minimum temperature $T_{\min }$ as the termination criteria. Instead, we terminate $S A M D S$ if the

current solution has not changed for $H$ steps. We set $H=\min \left(|V|, 10^{5}\right)$. Furthermore, we try 9 distinct pairs of cooling ratio $\lambda$ and epoch length $M$ derived from $\lambda \in\{0.99,0.999,0.9999\}$ and $M \in\{10,100,1000\}$. The best results achieved across different pairs of $\lambda$ and $M$ are reported. Although we implement $S A M D S$ in $\mathrm{C}++$, due to the time-consuming computations when selecting vertices probabilistically according to their degrees in each iteration, $S A M D S$ is too slow to process large graphs. Therefore, in addition to the termination criteria described above, we set a cut-off time of $10^{4}$ seconds to terminate its execution. On some graphs, $S A M D S$ fails to find a dominating set within the time limit, then the results are marked as "N/A".

We report the experimental results of minimum dominating set problem on the first and last graphs in alphabetical order from each of the 12 domains in Table 1.11 in this section. The complete results are given in Table A. 4 and Table A. 5 in Appendix A. Alg. 3 Campan et al. (2015), Alg. 4 Campan et al. (2015) and FastGreedy Eubank et al. (2004) algorithms are designed with focus on the efficiency. Their results are much worse than those of the other comparison algorithms on all the graphs. Due to the limited space, we do not report their results. Our results are the minimum vertex number of the solutions found by our algorithm with all distinct sets of parameters
each averaged over 10 runs.
As we can see, our algorithm achieves superior performance on all the 139 graphs. Specifically, on most graphs, our results are significantly better than those of all the comparison algorithms. On some small or sparse graphs, $G r R$ and $G r_{-} V$ ote tie with our algorithm. Gr_Rev achieves good results on a few graphs, but its overall performance is not as good as $G r R, G r_{-} V o t e$ and our algorithm. On some small or sparse graphs, the results of $S A M D S$ are close to those of $G r R, G r_{-} V o t e$ and our algorithm. On large or dense graphs, either $S A M D S$ can not return a valid dominating set within $10^{4}$ seconds, or its results are much worse than ours and those of the other comparison algorithms.

### 1.4.5 Discussion

## Parameter Setting

Our algorithms have three interactive parameters $\beta_{l}, \beta_{g}$ and $\gamma$. Unlike the parameters in machine learning models, those parameters do not need to be trained. Any combinations of valid values can be tried independently. We only need to compare the final solutions and return the best one. As the cooling ratio and epoch length of simulated annealing based algorithms, there are no choices of $\beta_{l}, \beta_{g}$ and $\gamma$ that will be good for all problems, and there is no general way to find the best choices for a given problem. Therefore, in general, when using our algorithms, the three parameters $\beta_{l}$, $\beta_{g}$ and $\gamma$ should be set with grid search.

With modern distributed computing technologies, theoretically speaking, using our algorithms is as easy as using the classic greedy approximation algorithms. However, in practice, we hope we can achieve good results by trying as few parameter combinations as possible. In this section, we analyze the effects of the three parameters of our algorithms in order to obtain some guidelines for choosing their values.

We first analyze the effects of $\beta_{l}, \beta_{g}$ and $\gamma$ in theory. Both $\beta_{l}$ and $\beta_{g}$ are exponent
parameters used to adjust the difference of local coverage efficiencies, i.e. LCEs. $\beta_{l}>1$ and $\beta_{g}>1$ increase the relative weight of larger $L C E$, while $\beta_{l}<1$ and $\beta_{g}<1$ works in the opposite way. For weighted set cover and minimum weighted dominating set problems, if $\beta_{l}$ and $\beta_{g}$ are too small, e.g. less than 0.5 , the difference of $L C E \mathrm{~s}$, which actually represents the underlying difference of the set weights and the set populations covering each item, will be minified too much. When $\beta_{l}=0$ and $\beta_{g}=0$, those differences are completely ignored, and there are no differences among sets and no difference among items. On the contrary, if $\beta_{l}$ and $\beta_{g}$ are too large, the difference of $L C E$ s will be magnified too much, which also adversely affects the solution quality. Therefore, we should avoid too small and too large values when choosing $\beta_{l}$ and $\beta_{g}$. For (unweighted) set cover and minimum dominating set problems, since the set weights are identical, we can try small values for $\beta_{l}$ and $\beta_{g}$, but it means the difference of set populations covering each item is more or less ignored. We should still avoid too large values for $\beta_{l}$ and $\beta_{g} . \gamma$ is used to adjust the relative weight of global coverage capacity $G C C$ when combining it with the local coverage gain $L C G$ to be the coverage benefit $C B$. Since the $G C C$ of each set is computed over all the items, while the $L C G$ is computed over only the currently uncovered items, with equal $\beta_{l}$ and $\beta_{g}, G C C$ is always greater than or equal to $L C G$. Their difference becomes larger in later iterations. Therefore, we should avoid too large values for $\gamma$ in case $G C C$ dominates $C B$.

Based on this analysis, we choose parameters with grid search in the previous experiments. Specifically, for weighted set cover and minimum weighted dominating set problems, we have 264 really distinct parameter combinations derived from $\beta_{l} \in$ $\{0.5,0.75,1,1.25,1.5,2,3,4\} ; \beta_{g} \in\{0.5,0.75,1,1.25,1.5,2,3,4\} ; \gamma \in\{0,0.01,0.1,1,10\}$. For (unweighted) set cover and minimum dominating set problems, we have 410 really distinct parameter combinations derived from $\beta_{l} \in\{0,0.25,0.5,0.75,1,1.25,1.5,2,3,4\}$; $\beta_{g} \in\{0,0.25,0.5,0.75,1,1.25,1.5,2,3,4\} ; \gamma \in\{0,0.01,0.1,1,10\}$.

In this section, we investigate the results of the previous experiments to further analyze the effects of $\beta_{l}, \beta_{g}$ and $\gamma$. For the weighted set cover problem, on each test instance, we obtain 264 results $r_{1}, r_{2}, r_{3}, \ldots, r_{264}$ by running our algorithm with the 264 distinct parameter combinations each averaged over 10 runs. Each result $r$ denotes the sum of set weights of the corresponding solution. In order to aggregate such results across different test instances from multiple data sets to obtain some overall statistical measures, we first normalize each $r$. Let $r_{\max }$ and $r_{\text {min }}$ denote the maximum and minimum results. Obviously, $r_{\max }$ corresponds to the worse solution, while $r_{\text {min }}$ corresponds to the best solution. We normalize each result $r$ to be

$$
\begin{equation*}
r^{\prime}=\frac{r_{\max }-r}{r_{\max }} \times 100 \tag{1.4-11}
\end{equation*}
$$

$r^{\prime}$ is actually the percentage of improvement of $r$ over the worse result $r_{\max }$ on the same test instance. Obviously, $r^{\prime}$ is in the range of $[0,100)$, and larger $r^{\prime}$ indicates better solution.

Since we run our algorithm with different parameter combinations and return the best results, it is worth examining the relationships between the best results and the individual parameter values. To this end, in addition to $r^{\prime}$, we normalize the result vector into an $0-1$ indicator vector, where 1 indicates the corresponding result $r$ is equal to $r_{\text {min }}$ and 0 indicates they are not equal.

Both the $r^{\prime}$ vector and the indicator vector can be aggregated across different test instances from different data sets. For the weighted set cover problem, we normalize the 264 results of our algorithm on each of the 70 test instances from the OR-Library data set. Then we stack the normalized $1 \times 264$ row vectors of $r^{\prime}$ and $0-1$ indicators into an $70 \times 264$ matrix $M R^{\prime}$ of $r^{\prime}$ and an $70 \times 264$ indicator matrix $M I$.

For $M R^{\prime}$, we first calculate the mean value of each column to obtain an $1 \times 264$ row vector $V R^{\prime}$. Then for each $\beta_{l}$ in $\{0.5,0.75,1,1.25,1.5,2,3,4\}$, we calculate the mean value of its corresponding values in $V R^{\prime}$. We call the obtained value as Average

Relative Solution Quality $(A R S Q)$ for $\beta_{l} . A R S Q \mathrm{~s}$ for $\beta_{l}$ reflect the effects of different $\beta_{l}$ on the solution quality. We calculate $A R S Q$ for $\beta_{g}$ and $\gamma$ in the same way.

For $M I$, we first calculate the mean value of each column to obtain an $1 \times 264$ row vector $V I$. Each element of $V I$ is the frequency of our algorithm achieves the best results with the corresponding parameter combination. Then for each $\beta_{l}$ in $\{0.5,0.75,1,1.25,1.5,2,3,4\}$, we calculate the mean value of its corresponding values in $V I$. We call the obtained value as Average Best Result Frequency $(A B R F)$ for $\beta_{l}$. $A B R F$ s reveal for which values of $\beta_{l}$ the best results are more likely to be achieved. We calculate $A B R F$ for $\beta_{g}$ and $\gamma$ in the same way.

We analyze the effects of $\beta_{l}, \beta_{g}$ and $\gamma$ in the same way for the (unweighted) set cover, minimum weighted dominating set and minimum (unweighted) dominating set problems. For the minimum weighted dominating set problem, we aggregate the $r^{\prime}$ vector and the indicator vector across different graphs from the BHOSLIB benchmark, DIMACS benchmark and Network Data Repository. The analytical results are shown in Figure 1.2, Figure 1.3, Figure 1.4 and Figure 1.5 . We use line charts to present the effects of $\beta_{l}$ and $\beta_{g}$. For $\gamma$, since the trial values, which are different from those of $\beta_{l}$ and $\beta_{g}$, are very unevenly distributed, we use separate bar charts to present its effects.

Apparently, the effects of $\beta_{l}, \beta_{g}$ and $\gamma$ are consistent for the 4 problems. Specifically, better performance is achieved with $\beta_{l}$ in range $[0.5,1]$. Beyond this range, especially with larger $\beta_{l}$, the performance becomes worse. For $\beta_{g}$, significantly better performance is achieved when its value is greater than 1 . When $\beta_{g}$ becomes even larger, the performance is improved less significantly. For $\gamma$, better performance is achieved with values less than 1. Note that the $A R S Q$ and $A B R F$ of $\gamma=0$ are overestimated. It is because when $\gamma=0$, different $\beta_{g}$ make no difference. We exclude those redundant parameter combinations in the experiments. Therefore, without the less effective parameter combinations that result in worse performance, e.g. $\beta_{l}>1$

Figure 1.2: Parameter Effect for Weighted Set Cover Problem

Figure 1.3: Parameter Effect for Set Cover Problem

Figure 1.4: Parameter Effect for Minimum Weighted Dominating Set Problem

Figure 1.5: Parameter Effect for Minimum Dominating Set Problem

and $\beta_{g}<1$, the $A R S Q$ and $A B R F$ of $\gamma=0$, which represent the average performance over different parameter combinations, are higher than those of the other $\gamma$ values.

Based these observations, we reduce the number of parameter combinations in our experiments. Specifically, we run our algorithms with three significantly smaller sets of parameter combinations. The first set is derived from $\beta_{l} \in\{0.5,0.75,1\}$; $\beta_{g} \in\{2,3,4\} ; \gamma \in\{0,0.1,1\}$. Since different $\beta_{g}$ make no difference when $\gamma=0$, there are a total of 21 really distinct combinations. The second set consists of 8 combinations derived from $\beta_{l} \in\{0.75,1\} ; \beta_{g} \in\{2,3\} ; \gamma \in\{0.1,1\}$. The third set contains only 1 combination. For weighted set cover and minimum weighted dominating set problems, it is $\beta_{l}=1, \beta_{g}=3, \gamma=0.1$, while for set cover and minimum dominating set problems, it is $\beta_{l}=0.75, \beta_{g}=3, \gamma=0.1$. The best results across different parameter combinations in each of these three sets are reported and compared to the results achieved with the original full sets of parameter combinations.

We run our algorithm for the weighted set cover problem on the 70 instances from OR-Library with the three smaller sets of parameter combinations. The results are given in Table 1.12 .

As we can see, with 21 and 8 parameter combinations, the results of our algorithm ("Ours (21)" and "Ours (8)") are very close to those achieved with 264 parameter combinations. In comparison to the competitors' results reported in Table 1.3 and Table 1.4. "Ours (21)" and "Ours (8)" results are still much better. Specifically, "Ours (21)" and "Ours (8)" results are better than the competitors' results on 64 instances. Some competitors can only tie with our algorithm on the rest 6 instances. With the second set of only 1 parameter combination, the results of our algorithm ("Ours (1)") are still very good. On most instances, "Ours (1)" results are close to those achieved with 264 parameter combinations. Moreover, "Ours (1)" results are better than the competitors' results on 61 instances. Some competitors tie with our algorithm on 6 other instances. On the rest 3 instances, i.e. scpb2, scpnre1 and

scpnrh3, "Ours (1)" results are slightly worse than those of some competitors, i.e. 86 vs 84,32 vs 30 and 67 vs 66 .

For the set cover problem, we run our algorithm on the 8 real world instances introduced in Table 1.5 with the three sets of parameter combinations. The results are given in Table 1.13. As we can see, with 21 and 8, or even just 1 parameter combination, the results of our algorithm are almost identical to those achieved with the full set of 410 parameter combinations.

For the minimum weighted dominating set problem and minimum dominating set problem, we run our algorithms on the 139 undirected simple graphs described in Table A. 1 in Appendix A with three sets of parameter combinations. We report the

results on the first and last graphs in alphabetical order from each of the 12 domains in Table 1.14 and Table 1.15 in this section. The complete results are given in Table A.6, Table A. 7 and Table A. 8 in Appendix A.

As we can see, with much smaller sets of parameter combination, our algorithms for minimum weighted dominating set problem and minimum dominating set problem can still achieve very good results.

In practice, we can consider the observations introduced above as guidelines for choosing appropriate parameter values for our algorithms, when computing time is important.

## Efficiency

In this section, we evaluate the efficiencies of our algorithms for the weighted set cover and minimum weighted dominating set problems by comparing their running time with those of the classic greedy algorithms .

Table 1.16:
Evaluation of Efficiency on 70 Instances of Weighted Set Cover Problem (consumed CPU time in seconds)

We run our algorithms and the corresponding classic greedy algorithms, which are all implemented with the same subroutines and data structures, e.g. max-heap, on the 70 instances from OR-Library and the 139 graphs from the Network Data Repository, and record the consumed CPU time. For our algorithms, since different parameters may affect the number of iterations needed to reach the full coverage in the second step, we run them with 8 different parameter combinations derived from $\beta_{l} \in\{0.75,1\} ; \beta_{g} \in\{2,3\} ; \gamma \in\{0.1,1\}$, which are chosen based on the guidelines introduced in Section 1.4.5, and report the average consumed CPU time.

The evaluation results of efficiency are given in Table 1.16 and Table 1.17. "Gr" column contains the consumed CPU time of the classic greedy algorithms, while "Ours" column contains those of our algorithms. As we can see, on all the 70 weighted set cover instances, our algorithm is slower than the classic greedy algorithm, while on 69 out of the 139 graphs for minimum weighted dominating set problem, our algorithm is significantly faster. The main reason is that, as we discuss in Section 1.3.3, our algorithms reduce the problem size after reserving the indispensable sets or vertices in this first step. This processing does not work for the 70 weighted set cover instances because they do not contain any indispensable sets. On the 69

graphs, however, it can significantly reduce the problem size. Therefore, although our algorithms generally have more iterations in the second step than the classic greedy algorithms, and have an extra third step, they can be very efficient when processing large real world instances.

### 1.5 Conclusion

I propose approximation algorithms for the weighted set cover and minimum weighted dominating set problems based on a novel greedy heuristic. Extensive experimental evaluations on a large number of synthetic and real world set cover instances and graphs from many domains demonstrate their superiority over state-of-the-art.

## CHAPTER 2

# Affinity Learning for Mixed Data Clustering 

### 2.1 Introduction

Clustering is the task of partitioning the data objects into a set of groups (clusters) such that objects in the same group are similar, while objects in different groups are dissimilar. It is one of the most fundamental problems in data mining and machine learning. Numerous algorithms have been developed for clustering. Most of them are designed to handle data with only one type of attributes, e.g. continuous, categorical or ordinal. Mixed data clustering has received relatively less attention, despite the fact that data with mixed types of attributes are common in real applications.

For mixed data clustering, one of the greatest challenges is how to measure the affinities or distances between data points. One of the most straightforward methods for processing mixed data is the so-called 1-hot or 1-of-K encoding. A categorical attribute with $K$ distinct values is encoded to $K 0-1$ binary attributes. Each categorical attribute value is transformed into a 1 on its corresponding binary attribute. Then they are treated just like continuous attributes. The more formal Gower's similarity coefficient Gower (1971) and its extensions Legendre \& Legendre (1998); Podani (1999) compute the partial affinity between two data points on each attribute according to the data type, and then aggregate all of them into a composite similarity measure. Such methods are widely used in practice. However, they essentially compute the affinity or distance "locally" between two data points, without considering the attribute values of other data points. This may result in missing some intrinsic information. For example, in many real world data sets, some values of a categori-
cal attribute are inherently related. Such information would be missed by similarity measures like Gower's coefficient, which simply assume different categories are totally independent and unrelated.

We propose a novel affinity learning based framework for mixed data clustering. It includes how to process data with mixed-type attributes, how to learn affinities between data points, and how to exploit the learned affinities for clustering.

First, each original attribute is represented with several abstract objects defined according to the specific data type and values. Each attribute value is then transformed into the initial affinities between the data point and the abstract objects of attribute. For categorical attributes, each category is defined as an abstract object. Its affinities to the data points in this category are initialized to a constant value. For each continuous attribute, two abstract objects are defined to represent its minimum and maximum values. Their initial affinities to each data point are transformed from the individual continuous attribute value with a novel method. For ordinal attributes, all possible values are first ranked and then replaced by their ranks. The new ordinal attributes are processed as continuous attributes.

After the data processing, we obtain a bipartite graph consisting of the data points, the abstract objects of attributes, and the initial affinities between them. The next step is to learn new affinities, including inferring the unknown affinities and refining the known affinities. We adopt the algorithm proposed in Li \& Latecki (2015), which essentially implements the von Neumann kernel Kandola et al. (2003) from the perspective of transitive inference confidence. Specifically, the new affinities are learned according to the transitive property of the affinitive relation. All the initial affinities are scaled with a common scaling factor. Any transitive inference process without self-loops is considered to be effective to reveal the two objects are affinitive. The confidence of such an inference process is quantified as the product of the related scaled affinity values. In general, there can be an infinite number of
distinct transitive inference processes between two objects. The confidence of all these inference processes are added up to be the new affinity between two objects. The details of this affinity learning algorithm are presented in Section 2.3.2.

In comparison to Gower's similarity coefficient and its extensions, our affinity learning method shares the similar idea of aggregating partial affinities on individual attributes into an overall measure. But the significant difference is that our affinities are computed "globally" by taking into account the interconnections among the attribute values of all data points, not just between the two data points. This is illustrated in Figure 2.1. The numbered blue circles represent data points, i.e. $\left\{\boldsymbol{x}_{\mathbf{1}}, \boldsymbol{x}_{\mathbf{2}}, \boldsymbol{x}_{\mathbf{3}}, \boldsymbol{x}_{\mathbf{4}}\right\}$. The two rectangles represent categorical attributes $R$ and $Y$, each of which has three distinct attribute values. If we compute the affinity $S_{i j}$ just between the two data points $\boldsymbol{x}_{\boldsymbol{i}}$ and $\boldsymbol{x}_{\boldsymbol{j}}$, like Gower's coefficient does, then $S_{13}$ and $S_{14}$ are both 0 , because they don't have any common attribute values. However, because of the existence of $\boldsymbol{x}_{\mathbf{2}}$, which shares one common attribute value with $\boldsymbol{x}_{\boldsymbol{1}}$ and $\boldsymbol{x}_{\boldsymbol{3}}$ respectively, it's intuitive to infer that $\boldsymbol{x}_{\boldsymbol{1}}$ is more affinitive to $\boldsymbol{x}_{\boldsymbol{3}}$ in comparison to $\boldsymbol{x}_{\boldsymbol{4}}$. Our affinity learning method can capture such information by taking into account all transitive inference processes, including $\boldsymbol{x}_{\mathbf{1}} \rightarrow R_{1} \rightarrow \boldsymbol{x}_{\mathbf{2}} \rightarrow Y_{2} \rightarrow \boldsymbol{x}_{\boldsymbol{3}}$.

The inferred affinities between data points can be used by many clustering algorithms. Alternatively, the refined affinities between data point and the abstract objects of attribute can be transformed into new data features. With such features, any algorithms can be used for clustering.

The mixed data clustering algorithms derived from the proposed framework achieve superior performance on many real world data sets. The details of the experimental evaluation are presented in Section 2.4 .

Figure 2.1:
An illustration of data point connections via their attribute values. Blue circles represent data points. Rectangles represent categorical attributes, each has three distinct attribute values.

### 2.2 Related Work

For mixed data clustering, in addition to using 1-hot encoding to obtain continuous features or Gower's coefficient Gower (1971) and its extensions Legendre \& Legendre (1998); Podani (1999) to measure the similarities between data points, as introduced in Section 2.1, there are also some specially designed clustering algorithms, including k-prototypes Z. Huang (1997, 1998), K-means-mixed Ahmad \& Dey (2007), CAVE Hsu \& Chen (2007), M-ART Hsu \& Huang (2008), INTEGRATE Böhm et al. (2010), INCONCO Plant \& Böhm (2011), SCENIC Plant (2012) and so on. K-prototypes algorithm Z. Huang (1997, 1998), which essentially follows the same idea of k-means algorithm, calculates the dissimilarity between two mixed-type objects as a combination of the squared Euclidean distance measure on the numeric attributes and the simple matching dissimilarity measure on the categorical attributes. K-means-mixed Ahmad \& Dey (2007), like k-prototypes, is also based on the k-means paradigm and
combines distance measures computed separately on numeric attributes and categorical attributes. Unlike k-prototypes, k-means-mixed does not assume a binary or a discrete measure between two distinct categorical attribute values but computes the distance as a function of their overall distribution and co-occurrence with other categorical attributes. This idea of computing distances "globally" is similar to ours, but it's only applied within categorical attributes. CAVE Hsu \& Chen (2007) uses variance to measure the similarity of the numeric part of the data and computes the similarity of the categorical part based on entropy weighted by the distances in the hierarchies. Similarly, the incremental clustering algorithm M-ART Hsu \& Huang (2008) also computes the distance between two data points according to distance hierarchies associated with the mixed-type attributes. INTEGRATE Böhm et al. (2010) applies ideas from information theory to implement the k-means paradigm. It models both numerical and categorical attributes with their probability distributions and minimizes a cost function based on the Minimum Description Length principle for clustering. INCONCO Plant \& Böhm (2011) and SCENIC Plant (2012) process mixed-type attributes in a similar way as INTEGRATE. Their main advantage is the capability of modeling and revealing the cluster-specific dependency patterns among the attributes.

To learn affinities between heterogeneous objects of data points and attributes, we adopt the algorithm proposed in Li \& Latecki (2015), which models the new affinities from the perspective of transitive inference confidence. It essentially implements the von Neumann kernel defined in Kandola et al. (2003). The idea of learning semantic similarity between terms from a corpus for measuring similarity between text documents in Kandola et al. (2003) is similar to our idea of capturing the intrinsic information between attribute values. One significant difference, besides the applications are different, is that we explicitly model the interconnections among data points and attribute values together. There are also some other algorithms can be used for
affinity learning , such as Zhou et al. (2003) and Yang et al. (2013). The main reasons we do not choose them include: 1. their row or column normalizations on the initial affinity matrix change the original relationships between the heterogeneous objects; and 2. they are not as semantically intuitive and meaningful as the one Li \& Latecki (2015) we adopt.

### 2.3 Our Framework

### 2.3.1 Mixed Data Processing

We first transform the data points and their mixed-type attribute values into abstract objects and initial affinities. For categorical attributes, each category is defined as an abstract object. Its affinities to the data points in this category are initialized to 1 , while its initial affinities to the rest data points are 0 . This is similar to the 1-hot encoding. For each continuous attribute $C$, two abstract objects are defined to represent its minimum and maximum values, i.e. $C_{\min }$ and $C_{\max }$. The attribute value $x_{C}$ of the data point $\boldsymbol{x}$ is transformed into two initial affinities to the abstract objects of $C_{\min }$ and $C_{\max }$. Suppose they are $S_{\boldsymbol{x}, C_{\min }}=a$ and $S_{\boldsymbol{x}, C_{\max }}=b$, we have two requirements,

$$
\left\{\begin{array}{l}
a^{2}+b^{2}=1  \tag{2.3-1}\\
\left(C_{\min } \times a+C_{\max } \times b\right) /(a+b)=x_{C}
\end{array}\right.
$$

To understand the first requirement, consider the illustration in Figure 2.2, $a, b, c, d$ on the edges represent the initial affinities of two data points $\boldsymbol{x}$ and $\boldsymbol{x}^{\prime}$ to the abstract objects of $C_{\min }$ and $C_{\max }$ respectively. The diffusion based affinity learning algorithms essentially compute the affinity $S_{x, x^{\prime}}$ as

$$
\begin{equation*}
S_{\boldsymbol{x}, \boldsymbol{x}^{\prime}}=a \times c+b \times d \tag{2.3-2}
\end{equation*}
$$

Figure 2.2:
An illustration for explaining the first requirement in equation (2.3-1) for transforming a continuous attribute value into initial affinities.

If $\boldsymbol{x}$ and $\boldsymbol{x}^{\prime}$ have the same attribute value $x_{C}$ on $C$, obviously their affinities to $C_{\min }$ and $C_{\max }$ should be the same, i.e. $a=c$ and $b=d$. It's also obvious to require that $S_{x, x^{\prime}}$ to be a constant, e.g. 1 , no matter what the attribute value $x_{C}$ is. Therefore, we get the first requirement,

$$
\begin{equation*}
S_{\boldsymbol{x}, \boldsymbol{x}^{\prime}}=a \times c+b \times d=a \times a+b \times b=1 \tag{2.3-3}
\end{equation*}
$$

The second requirement makes sure the original attribute value can be restored from the transformed affinities.

Specifically, to transform the attribute value $x_{C}$ of $\boldsymbol{x}$ into the initial affinities, $x_{C}$ is first scaled with the Min-Max normalization.

$$
\begin{equation*}
x_{C}^{\prime}=\frac{x_{C}-C_{\min }}{C_{\max }-C_{\min }} \tag{2.3-4}
\end{equation*}
$$

The scaled attribute value $x_{C}^{\prime}$ is in range [0, 1], i.e. $C_{\min }^{\prime}=0$ and $C_{\max }^{\prime}=1$. We have

$$
\left\{\begin{array}{l}
a^{2}+b^{2}=1  \tag{2.3-5}\\
(0 \times a+1 \times b) /(a+b)=x_{C}^{\prime}
\end{array}\right.
$$

Solve the system of equations, we get the affinity transformation formula as

$$
\left\{\begin{array}{l}
a=\sqrt{\left(1-x_{C}^{\prime}\right)^{2} /\left(2 \times{x_{C}^{\prime}}^{2}-2 \times x_{C}^{\prime}+1\right)}  \tag{2.3-6}\\
b=\sqrt{x_{C}^{\prime} /\left(2 \times{x_{C}^{\prime}}^{2}-2 \times x_{C}^{\prime}+1\right)}
\end{array}\right.
$$

In this way, if two data points have the same value on a continuous attribute, their partial affinity inferred by the diffusion based affinity learning algorithm described below based on this agreement is always the same, no matter what the value is.

For ordinal attributes, all possible values are first ranked and then replaced by their ranks. The new ordinal attributes are processed as continuous attributes.

If an attribute value of $\boldsymbol{x}$ is missing, the related initial affinities are all set to 0 .

### 2.3.2 Affinity Learning

Now we have a bipartite graph consisting of $n$ data points, $m$ abstract objects of attribute, and the initial affinities between them. We construct a nonnegative symmetric affinity matrix $A=\left(a_{i j}\right)_{\alpha \times \alpha}$, where $\alpha=m+n$.

$$
A=\left[\begin{array}{ll}
A_{D D} & A_{D C}  \tag{2.3-7}\\
A_{C D} & A_{C C}
\end{array}\right]
$$

where $A_{D D}$ is a $n \times n$ zero matrix indicating that the affinities between data points are unknown; $A_{D C}=A_{C D}^{\top}$ is a $n \times m$ matrix consisting of the initial affinities between data points and the abstract objects of attributes; $A_{C C}$ is a $m \times m$ zero matrix indicating that the affinities between abstract objects of attributes are unknown.

The next step is to scale the nonzero entries in $A$, i.e. the initial affinities, with a common scaling factor $\Delta$ which satisfies

$$
\begin{equation*}
\Delta>\max \left(a_{\max }, \rho(A)\right) \tag{2.3-8}
\end{equation*}
$$

where $a_{\max }$ is the maximum entry of $A ; \rho(A)$ is the spectral radius of $A$.
Each entry $a_{i j}$ of $A$ is scaled with $\Delta$ to obtain another matrix $A^{\prime}=\left(a_{i j}^{\prime}\right)_{\alpha \times \alpha}$ where

$$
\begin{equation*}
a_{i j}^{\prime}=\frac{a_{i j}}{\Delta} \tag{2.3-9}
\end{equation*}
$$

Obviously, any entry $a_{i j}^{\prime}$ of $A^{\prime}$ is less than 1 . Also, the spectral radius of $A^{\prime}$ is less than 1. Therefore,

$$
\begin{equation*}
\lim _{l \rightarrow \infty}\left(A^{\prime}\right)^{l}=\mathbf{0} \tag{2.3-10}
\end{equation*}
$$

Then we compute a matrix $A^{*}$ as

$$
\begin{equation*}
A^{*}=\left(I-A^{\prime}\right)^{-1} \tag{2.3-11}
\end{equation*}
$$

where $I$ is the $\alpha \times \alpha$ identity matrix.
Each entry $a_{i j}^{*}$ of $A^{*}$ denotes a value,

$$
\begin{equation*}
a_{i j}^{*}=\sum_{l=0}^{\infty}\left[\left(A^{\prime}\right)^{l}\right]_{i j} \tag{2.3-12}
\end{equation*}
$$

which is the learned affinity between objects $i$ and $j$.
The inferred affinities between data points are in $A_{D D}^{*}$. The refined affinities between data points and abstract objects of attributes are in $A_{D C}^{*}$.

To get the scaling factor $\Delta$, we need to calculate the spectral radius $\rho(A)$ of $A$. With iterative eigenvalue algorithms, it can be done in $\mathcal{O}\left(\alpha^{2}\right)$. Scaling the nonzero entries of $A$ takes $\mathcal{O}\left(\alpha^{2}\right)$. The straightforward computation for inverting the matrix $I-A^{\prime}$ takes $\mathcal{O}\left(\alpha^{3}\right)$. Advanced algorithms, such as Strassen algorithm, can further reduce the asymptotic computational complexity. Therefore, the straightforward time complexity of our affinity learning algorithm is $\mathcal{O}\left(\alpha^{3}\right)$. However, $A$ and $I-A^{\prime}$ are usually very sparse. Consequently, the practical efficiency should be much better.

We evaluate it on several real data sets with $\alpha$ up to about 30,000 . The details are presented in Section 2.4

### 2.3.3 Clustering with Learned Affinities

In this work, we use the complete-linkage algorithm for clustering with the inferred affinities between data points in $A_{D D}^{*}$. It is one of the agglomerative hierarchical clustering methods. Specifically, in the beginning, each data point is in a cluster of its own. Then these clusters are iteratively combined until the target cluster number is reached. At each step, the two clusters, whose two members (one in each cluster) have the minimum pair-wise affinity, are combined.

Alternatively, the refined affinities of data points to the abstract objects of attributes can be used as new data features. Specifically, in the $n \times m$ matrix $A_{D C}^{*}$, each row is considered as a $m$-dimensional feature vector of the corresponding data point. In this work, we choose k-means algorithm and complete-linkage algorithm for clustering with such features.

### 2.4 Experimental Evaluation

### 2.4.1 Experimental Setup

We evaluate the performance of the proposed clustering framework on several real world data sets from the UCI Machine Learning Repository, including 5 mixedtype (Acute Inflammations, Heart Disease, Credit Approval, Contraceptive Method Choice and Adult) and 2 categorical (Soybean and Tic-Tac-Toe Endgame). The detailed information of these data sets is summarized in Table 2.1.

Each record of Acute Inflammation data set corresponds to the yes or no diagnoses of two diseases of the urinary system. We transform the two diagnoses into four classes, i.e. (yes,yes), (yes,no), (no,yes) and (no,no). For Adult data set, we only

Table 2.1:
Data Sets for Experimental Evaluation (number of different types of attributes, number of instances and number of classes)

| Data set | Continuous | Categorical | Ordinal | \#Instance | \#Class |
| :--- | :---: | :---: | :---: | :---: | :---: |
| Acute Inflammations | 1 | 5 | - | 120 | 4 |
| Heart Disease | 6 | 6 | 1 | 270 | 2 |
| Credit Approval | 6 | 9 | - | 690 | 2 |
| Contraceptive Method Choice | 2 | 7 | - | 1,473 | 3 |
| Adult | 6 | 8 | - | 48,842 | 2 |
| Soybean | - | 35 | - | 47 | 4 |
| Tic-Tac-Toe Endgame | - | 9 | - | 958 | 2 |

use the training set, which contains 32,561 records. For fair comparison, we remove the records with missing attribute values. The final data set contains 30,162 records. We skip the attribute "education", because it is fully expressed by another attribute "education-num". In Credit Approval data set, 37 (about \%5) records have one or more missing values. We simply remove them.

The clustering algorithms derived from the proposed framework include: 1. IA $+\mathbf{C L}$ (Inferred Affinities between data points + Complete-Linkage algorithm); 2. FRA+CL (Feature from Refined Affinities of the data point to the abstract objects of attributes + Complete-Linkage algorithm); 3. FRA + KM (Feature from Refined Affinities of the data point to the abstract objects of attributes $+\mathbf{K}$-Means algorithm).

For the three derived clustering algorithms, we vary the scaling factor $\Delta$ in equation 2.3-9 in the range of $\left(\max \left(a_{\max }, \rho(A)\right), 4 \times \max \left(a_{\max }, \rho(A)\right)\right.$ ] (see equation (2.3-8) with a step size of 10 . The best results achieved by each algorithm in this process are reported. For FRA+CL and FRA+KM, we use the squared Euclidean distance measure.

The comparison algorithms include: 1. $\mathbf{O H}+\mathbf{C L}$ (Feature from $\mathbf{O n e - H o t}$ encoding + Complete-Linkage algorithm); 2. OH $+\mathbf{K M}$ (Feature from One-Hot encoding $+\mathbf{K}$-Means algorithm); 3. GC+CL (Gower's Coefficient + Complete-Linkage algorithm); 4. KP (k-prototypes) Z. Huang (1997, 1998); 5. KMM (K-means-mixed)

Ahmad \& Dey (2007). These algorithms are widely used in practice for mixed data clustering. Some of them are still state-of-the-art in performance. Many recent algorithms, such as Plant \& Böhm (2011); Plant (2012) are very complex to be implemented. We are not able to obtain the source code from the authors.

The Gower's coefficient in GC+CL processes ordinal attributes according to Eqs. 2a-b of Podani (1999). For KP (k-prototypes), we scale all numeric attributes to the range of $[0,1]$ with Min-Max normalization and randomly select $k$ data points without missing values to be the initial prototypes. The parameter $\gamma$ is varied from 0.5 to 1.5 with a step size of 0.1 for the 5 mixed-type data sets. When using k-means technique, including k-prototypes and K-means-mixed, the maximum number of iterations is set to be 1000 for the Adult data set, which contains much more data, and 100 for the other 6 data sets. Moreover, all the tests are run for 100 times and the average results are reported.

For all the clustering algorithms above, we set the target number of clusters to be the number of classes in each data set. The clustering quality is measured in terms of Jaccard Coefficient, Fowlkes and Mallows Index, and FScore Jing et al. (2007). The results are consistent, so only FScore is reported. Suppose $k$ is the class and cluster number, $n$ is the number of data points, $n_{i}$ and $n_{j}$ are the numbers of data points in class $C L A_{i}$ and cluster $C L U_{j}$ respectively, $n_{i j}$ is the number of data points in both $C L A_{i}$ and $C L U_{j}$, FScore is defined as

$$
\begin{equation*}
F \text { Score }=\sum_{i=1}^{k}\left(\frac{n_{i}}{n} \times \max _{1 \leq j \leq k} \frac{2 \times R_{i j} \times P_{i j}}{R_{i j}+P_{i j}}\right) \tag{2.4-13}
\end{equation*}
$$

where $R_{i j}=n_{i j} / n_{i}$ and $P_{i j}=n_{i j} / n_{j}$.
All the experiments are implemented in MATLAB R2016a and conducted on a PC with $\operatorname{Intel}(\mathrm{R})$ Core(TM) i7 processor up to 3.4 GHz and 16GB RAM.

### 2.4.2 Experimental Results

As shown in Table 2.2, the three clustering algorithms derived from the proposed framework achieve superior performance (with ties) on all the 7 data sets. Apparently, among these three algorithms, IA+CL is the best. It achieves the best performance on 5 data sets. In comparison to GC+CL, the performance of IA+CL is consistently better (with ties). Since they use the same clustering algorithm, it proves that our inferred affinities between data points, which are computed "globally", capture more useful information than the "locally" computed similarities. We can see FRA+CL is consistently better (with ties) than $\mathrm{OH}+\mathrm{CL}$, and $\mathrm{FRA}+\mathrm{KM}$ is consistently better (with ties) than $\mathrm{OH}+\mathrm{KM}$. It means the feature derived from the refined affinities of the data point to the abstract objects of attributes, which is also computed "globally" in our framework, is more effective than the 1-hot encoding feature. On some data sets, the performance of KP and KMM are competitive. But overall, our IA+CL and FRA+CL are superior. Obviously, the algorithms derived from the proposed framework are effective for mixed data clustering.

In order to further prove that it is beneficial to take into account the interconnections among the attribute values of all data points, we compare the performance of IA + CL, FRA+CL and FRA+KM, which are reported in Table 2.2, with those

achieved with "locally" inferred affinities and features from non-refined affinities. Specifically, after scaling the initial affinities with equation 2.3-9, we obtain the matrix $A^{\prime} . A_{D C}^{\prime}$ contains the non-refined affinities of data points to the abstract objects of attributes. We use them as data feature (FNRA: Feature from Non-Refined Affinities) for clustering with the complete-linkage (CL) and k-means (KM) algorithms. To obtain the "local" affinities between data points, we compute $A^{*}=A^{\prime} \times A^{\prime}$. The affinities in $A_{D D}^{*}$ are inferred "locally" just between each pair of data points. We call them LIA (Locally Inferred Affinities) and use the complete-linkage (CL) algorithm for clustering. When comparing LIA+CL versus IA+CL, FNRA+CL versus FRA + CL and FNRA + KM versus FRA + KM, on each data set, LIA + CL, FNRA + CL and FNRA + KM use the same scaling factors $\Delta$ as IA + CL, FRA+CL and FRA+KM respectively. Table 2.3 shows the performance comparisons. As we can see, the performance of using "globally" inferred or refined affinities are always better or equal to those of using "locally" inferred or non-refined affinities. It demonstrates that the proposed framework is effective for modeling and exploiting the interconnections among the attribute values of all data points to improve clustering performance.

In order to show that the proposed framework for mixed data clustering is applicable in practice, we evaluate its efficiency on real world data sets. The proposed

Table 2.4: Time Consumed on Affinity Learning (sec.)

| Data set | \#Instance | \#Attribute | \#Object | Time Consumed |
| :--- | :---: | :---: | :---: | :---: |
| Acute Inflammations | 120 | 6 | 132 | 0.005 |
| Heart Disease | 270 | 13 | 300 | 0.01 |
| Credit Approval | 653 | 15 | 705 | 0.03 |
| Contraceptive Method Choice | 1473 | 9 | 1493 | 0.09 |
| Adult | 30,162 | 13 | 30,256 | 40 |
| Soybean | 47 | 35 | 105 | 0.005 |
| Tic-Tac-Toe Endgame | 958 | 9 | 985 | 0.04 |

framework consists of three main components: 1. processing mixed data; 2. learning affinities; 3. clustering with the learned affinities. As introduced in Section 2.3.1, it takes linear time to process the mixed data. When clustering with the learned affinities, the time complexity totally depends on the selected clustering algorithm. Therefore, we only evaluate the efficiency of affinity learning. The average time consumed on this step in the clustering experiments are reported in Table 2.4.

As shown in Table 2.4, for small data sets, which contain at most thousands of objects, the time consumed on affinity learning is negligible. For medium data sets, such as Adult, it may take a few minutes. Since these results are obtained on an ordinary PC, we can say, with modern computation technologies and computing power, the proposed framework is applicable in practice.

### 2.5 Conclusions

The main contributions of this work include: 1. we develop a novel framework for mixed data clustering; 2. our approach to mixed data processing, especially the way we transform continuous attribute values into initial affinities, is novel; 3. it's novel to transform the refined affinities between data points and the abstract objects of attributes into new data features. Experimental results on several real world data sets demonstrate the proposed framework is effective.

## CHAPTER 3

# Clustering Aggregation as Maximum-Weight Independent Set 

### 3.1 Introduction

Clustering is a fundamental problem in data analysis, and has extensive applications in artificial intelligence, statistics and even in social sciences. The goal is to partition the data objects into a set of groups (clusters) such that objects in the same group are similar, while objects in different groups are dissimilar.

In the past few decades, many different clustering algorithms have been developed. Some popular ones include K-means, DBSCAN, Ward's algorithm, EM-clustering and so on. However, there are potential shortcomings for each of the known clustering algorithms. For instance, K-means Lloyd (1982) and its variations have difficulty detecting the "natural" clusters, which have non-spherical shapes or widely different sizes or densities. Furthermore, in order to achieve good performance, they require an appropriate number of clusters as the input parameter, which is usually very hard to specify. DBSCAN Ester et al. (1996), a density-based clustering algorithm, can detect clusters of arbitrary shapes and sizes. However, it has trouble with data which have widely varying densities. Also, DBSCAN requires two input parameters specified by the user: the radius, Eps, to define the neighborhood of each data object, and the minimum number, minPts, of data objects required to form a cluster.

Clustering aggregation, also known as consensus clustering or clustering ensemble, refers to a kind of methods which try to find a single (consensus) superior clustering
from a number of input clusterings obtained by different algorithms with different parameters. The basic motivation of these methods is to combine the advantages of different clustering algorithms and overcome their respective shortcomings. Besides generating stable and robust clusterings, consensus clustering methods can be applied in many other scenarios, such as categorical data clustering, "privacy-preserving" clustering and so on. Some representative methods include Gionis et al. (2007); Strehl \& Ghosh (2002a); Fred \& Jain (2002); Singh et al. (2008); Nguyen \& Caruana (2007); Fern \& Brodley (2004); Topchy et al. (2003); Mimaroglu \& Erdil (2011); D. Huang et al. (2015, 2016b a). Strehl \& Ghosh (2002a) formulates clustering ensemble as a combinatorial optimization problem in terms of shared mutual information. That is, the relationship between each pair of data objects is measured based on their cluster labels from the multiple input clusterings, rather than the original features. Then a graph representation is constructed according to these relationships, and finding a single consolidated clustering is reduced to a graph partitioning problem. Similarly, in Gionis et al. (2007), a number of deterministic approximation algorithms are proposed to find an "aggregated" clustering which agrees as much as possible with the input clusterings. Fred \& Jain (2002) also applies a similar idea to combine multiple runs of K-means algorithm. Singh et al. (2008) proposes to capture the notion of agreement using an measure based on a 2D string encoding. They derive a nonlinear optimization model to maximize the new agreement measure and transform it into a strict 0-1 Semidefinite Program. Nguyen \& Caruana (2007) presents three iterative EM-like algorithms for the consensus clustering problem. The COMUSA algorithm proposed in Mimaroglu \& Erdil (2011) first constructs a similarity graph based on the co-association matrix. Then it identifies new clusters by iteratively selecting a pivot data object and expanding the cluster with its immediate free neighbors which are most similar to the pivot. D. Huang et al. (2015) proposed two algorithms termed weighted evidence accumulation clustering (WEAC) and graph
partitioning with multi-granularity link analysis (GP-MGLA). WEAC integrates the reliability of each base clustering into the co-association matrix and uses agglomerative algorithms to obtain the final clustering. GP-MGLA models the three levels of granularity in clustering aggregation, i.e., data objects, clusters and base clusterings, in a single bipartite graph, and partitions it to divide data objects into the final clusters. D. Huang et al. (2016b) proposed to sparsify the co-association matrix of "microcluster" with the k-nearest neighbors strategy and learn new similarities based on random walks. Two algorithms, probability trajectory accumulation (PTA) and probability trajectory based graph partitioning (PTGP) were proposed to obtain the final clustering with the learned similarities. PTA is based on agglomerative algorithms, while PTGP is based on the graph partitioning technique. D. Huang et al. (2016a) formulated clustering aggregation as a binary linear programming problem and proposed a solver based on max-product belief propagation on a factor graph.

A common feature of these consensus clustering methods is that they usually do not access to the original features of the data objects. They utilize the cluster labels in different input clusterings as the new features of each data object to find an optimal clustering. Consequently, the success of these consensus clustering methods heavily relies on a premise that the majority of the input clusterings are reasonably good and consistent, which is not often the case in practice. For example, given a new challenging dataset, it is probable that only some few of the chosen underlying clustering algorithms can generate good clusterings. Many moderate or even bad input clustering can mislead the final "consensus". Furthermore, even if we choose the appropriate underlying clustering algorithms, in order to obtain good input clusterings, we still have to specify the appropriate input parameters. Therefore, it is desired to devise new consensus clustering methods which are more robust and do not need the optimal input parameters to be specified.

Our definition of "clustering aggregation" is different. Informally, for each of the
clusters in the input clusterings, we evaluate its quality with some internal indices measuring both the cohesion and separation. Then we select an optimal subset of clusters, which partition the dataset together and have the best overall quality, as the "aggregated clustering". (We give a formal statement of our "clustering aggregation" problem in Section (3.2). In this framework, ideally, we can find the optimal "aggregated clustering" even if only a minority of the input clusterings are good enough. Therefore, we only need to specify an appropriate range of the input parameters, rather than the optimal values, for the underlying clustering algorithms.

We formulate this "clustering aggregation" problem as a special instance of MaximumWeight Independent Set (MWIS) problem. An attributed graph is constructed from the union of the input clusterings. The vertices, which represent the distinct clusters, are weighted by an internal index measuring both cohesion and separation. The edges connect the vertices whose corresponding clusters overlap (In practice, we may tolerate a relatively small amount of overlap for robustness). Then selecting an optimal subset of non-overlapping clusters partitioning the dataset together can be formulated as seeking the MWIS of the attributed graph, which is the heaviest subset of mutually non-adjacent vertices. Moreover, this MWIS problem exhibits a special structure. Since the clusters of each input clustering form a partition of the dataset, the vertices corresponding to each clustering form a maximal independent set (MIS) in the attributed graph.

The most important source of motivation for this work is Brendel \& Todorovic (2010). In Brendel \& Todorovic (2010), image segmentation is formulated as a MWIS problem. Specifically, given an image, they first segment it with different bottomup segmentation schemes to get an ensemble of distinct superpixels. Then they select a subset of the most "meaningful" non-overlapping superpixels to partition the image. This selection procedure is formulated as solving a MWIS problem. In this respect, our work is very similar to Brendel \& Todorovic (2010). The only difference
is that our work applies the MWIS formulation to a more general problem, clustering aggregation.

The maximum-weight independent set problem, which is complementary to the maximum-weight clique problem, is known to be NP-hard. Many heuristic or local search algorithms are proposed to find the approximate solutions. Some of the most effective algorithms include LSCC and LSCC+BMS Y. Wang et al. (2016), FastWClq Cai \& Lin (2016), WLMC Jiang et al. (2017) and RRWL Fan et al. (2017). They are all proposed for solving the maximum-weight clique problem. Obviously, they can also be used for solving the maximum-weight independent set problem. LSCC and LSCC + BMS Y. Wang et al. (2016) consist of two phases: (1) randomly generating a maximal clique $C$ and then (2) improving $C$ in a deterministic way. In each local move, they select the neighboring clique with the greatest weight according to the strong configuration checking criterion. FastWClq Cai \& Lin (2016) interleaves between clique construction and graph reduction. WLMC Jiang et al. (2017) is an exact branch-and-bound algorithm. It exploits a novel preprocessing to derive an initial vertex ordering and to reduce the size of the graph, and incremental vertex-weight splitting to reduce the number of branches in the search space. RRWL Fan et al. (2017) uses the restart and the random walk strategies to improve local search. If a solution is revisited in some particular situation, the search will restart. In addition, when the local search has no other options except dropping vertices, it will use random walk.

As we mentioned before, in the context of clustering aggregation, the formulated MWIS problem exhibits a special structure. That is, the vertices corresponding to each clustering form a maximal independent set (MIS) in the attributed graph. This special structure is valuable for finding good approximations to the MWIS because, although these MISs may not be the global optimum of the MWIS, they are close to distinct local optimums. We propose a variant of simulated annealing method that
takes advantage of this special structure. Our algorithm, simulated annealing based on maximal independent set (SAMIS), starts from each MIS and utilizes a local search heuristic to explore its neighborhood in order to find better approximations to the MWIS. The best solution found in this process is returned as the final approximate MWIS. Since the exploration for each MIS is independent, our algorithm is suitable for parallel computation.

Finally, since the selected clusters may not be able to cover the entire dataset, our approach performs a post-processing to assign the missing data objects to their nearest clusters.

### 3.2 Our Work

Consider a set of $n$ data objects $D=\left\{d_{1}, d_{2}, \ldots, d_{n}\right\}$. A clustering $C_{i}$ of $D$ is obtained by applying an exclusive clustering algorithm with a specific set of input parameters on $D$. The disjoint clusters $c_{i 1}, c_{i 2}, \ldots, c_{i k}$ of $C_{i}$ are a partition of $D$, i.e. $\bigcup_{j=1}^{k} c_{i j}=D$ and $c_{i p} \cap c_{i q}=\emptyset$ for all $p \neq q$.

With different clustering algorithms and different parameters, we can obtain a set of $m$ different clusterings of $D: C_{1}, C_{2}, \ldots, C_{m}$. For each cluster $c_{i j}$ in the union of these $m$ clusterings, we evaluate its quality with an internal index measuring both cohesion and separation.

We use the average silhouette coefficient of a cluster as such an internal index in this work. The silhouette coefficient is defined for an individual data object. It is a measure of how similar that data object is to data objects in its own cluster compared to data objects in other clusters. Formally, the silhouette coefficient for the $t^{\text {th }}$ data object, $S_{t}$, is defined as

$$
\begin{equation*}
S_{t}=\frac{b_{t}-a_{t}}{\max \left(a_{t}, b_{t}\right)} \tag{3.2-1}
\end{equation*}
$$

where $a_{t}$ is the average distance from the $t^{t h}$ data object to the other data objects
in the same cluster as $t$, and $b_{t}$ is the minimum average distance from the $t^{t h}$ data object to data objects in a different cluster, minimized over clusters.

Silhouette coefficient ranges from -1 to +1 and a positive value is desirable. The quality of a particular cluster $c_{i j}$ can be evaluated with the average of the silhouette coefficients of the data objects belonging to it.

$$
\begin{equation*}
A S C_{c_{i j}}=\frac{\sum_{t \in c_{i j}} S_{t}}{\left|c_{i j}\right|} \tag{3.2-2}
\end{equation*}
$$

where $S_{t}$ is the silhouette coefficient of the $t^{t h}$ data object in cluster $c_{i j},\left|c_{i j}\right|$ is the cardinality of cluster $c_{i j}$.

We select an optimal subset of non-overlapping clusters from the union of all the clusterings, which partition the dataset together and have the best overall quality, as the "aggregated clustering". The selection of clusters is formulated as a special instance of the Maximum-Weight Independent Set (MWIS) problem.

Formally, consider an undirected and weighted graph $G=(V, E)$, where $V=$ $\{1,2, \ldots, n\}$ is the vertex set and $E \subseteq V \times V$ is the edge set. For each vertex $i \in V$, a positive weight $w_{i}$ is associated with $i . A=\left(a_{i j}\right)_{n \times n}$ is the adjacency matrix of $G$, where $a_{i j}=1$ if $(i, j) \in E$ is an edge of $G$, and $a_{i j}=0$ if $(i, j) \notin E$. A subset of $V$ can be represented by an indicator vector $\mathbf{x}=\left(x_{i}\right) \in\{0,1\}^{n}$, where $x_{i}=1$ means that $i$ is in the subset, and $x_{i}=0$ means that $i$ is not in the subset. An independent set is a subset of $V$, whose elements are pairwise nonadjacent. Then finding a maximumweight independent set, denoted as $\mathbf{x}^{*}$ can be posed as the following:

$$
\begin{align*}
& \mathbf{x}^{*}=\operatorname{argmax}_{\mathbf{x}} \mathbf{w}^{\mathbf{T}} \mathbf{x}  \tag{3.2-3}\\
& \text { s.t. } \forall i \in V: x_{i} \in\{0,1\}, \quad \mathbf{x}^{T} A \mathbf{x}=0
\end{align*}
$$

The weight $w_{i}$ on vertex $i$ is defined as:

$$
\begin{equation*}
w_{i}=A S C_{c_{i}} \times\left|c_{i}\right| \tag{3.2-4}
\end{equation*}
$$

where $c_{i}$ is the cluster represented by vertex $i, A S C_{c_{i}}$ and $\left|c_{i}\right|$ are its quality measure and cardinality respectively.

Our problem (3.2-3) is a special instance of MWIS problem, since graph $G$ exhibits an additional structure, which we will unitize in the proposed algorithm. The vertex set $V$ can be partitioned into disjoint subsets $\mathbf{P}=\left\{P_{1}, P_{2}, \ldots, P_{m}\right\}$, where $P_{i}$ corresponds to the clustering $C_{i}$, such that each $P_{i}$ is also a maximal independent set (MIS), which means it is not a subset of any other independent set. This follows from the fact that each clustering $C_{i}$ is a partition of the dataset $D$. Formally,

$$
\begin{equation*}
\bigcup_{i=1}^{m} P_{i}=V, \quad P_{i} \cap P_{j}=\emptyset, \quad i \neq j, \quad \text { and } \quad P_{i} \quad \text { is MIS }, \quad \forall i, j \in\{1,2, \ldots, m\} \tag{3.2-5}
\end{equation*}
$$

The basic idea of our maximum-weight independent set algorithm is to explore the neighborhood of each known MIS $P_{i}$ independently with a local search heuristic in order to find better solutions. The proposed algorithm is an instance of simulated annealing methods Kirkpatrick et al. (1983) with multiple initializations.

Our algorithm starts with a particular MIS $P_{i}$, denoted by $x_{0} . x_{t+1}$, which is a neighbor of $x_{t}$, is obtained by replacing some lower-weight vertices in $x_{t}$ with higherweight vertices under the constraint of always being an independent set. Specifically, we first reduce $x_{t}$ by removing a proportion $q$ of lower-weight vertices. Here we remove a proportion, rather than a fixed number, of vertices in order to make the reduction adaptive with respect to the number $s$ of vertices in $x_{t}$. In practice, we use ceil $(s \times q)$ to make sure at least one vertex will be removed. Note that this step is probabilistic, rather than deterministic. The probability that a vertex $i$ will be
retained is proportional to its $W D$ value, which is defined as follows.

$$
\begin{equation*}
W D_{i}=\frac{w_{i}}{\sum_{j \in N_{i}} w_{j}} \tag{3.2-6}
\end{equation*}
$$

where $N_{i}$ is the set of vertices which are connected with vertex $i$ in $G$.
Intuitively, larger $W D$ value indicates larger weight, less conflict with other vertices or both. Therefore, the obtained $x_{t}^{\prime}$ is likely to contain vertices with large weights and have large potential room for improvement. The parameter of proportion $q$ is used to control the "radius" of the neighborhood to be explored.

Then our algorithm iteratively improves $x_{t}^{\prime}$ by adding compatible vertices one by one. In each iteration, it first identifies all the vertices compatible with the existing ones in current $x_{t}^{\prime}$, called candidates. Then a "local" measure $W D^{\prime}$ is calculated to evaluate each of these candidates:

$$
\begin{equation*}
W D_{i}^{\prime}=\frac{w_{i}}{\sum_{j \in N_{i}^{\prime}} w_{j}} \tag{3.2-7}
\end{equation*}
$$

where $N_{i}^{\prime}$ is the set of candidate vertices which are connected with vertex $i$.
The large value of $W D_{i}^{\prime}$ indicates that candidate $i$ either can bring large improvement this time (numerator) or has small conflict with further improvements (denominator) or both.

The candidate with the largest $W D^{\prime}$ value is added to $x_{t}^{\prime}$. In next iteration, this new $x_{t}^{\prime}$ will be further improved. This iterative procedure continues until $x_{t}^{\prime}$ cannot be further improved. We obtain $x_{t}^{\prime}$ as a randomized neighbor of $x_{t}$.

Now our algorithm calculates the acceptance ratio $\alpha=e^{\left(W\left(x_{t}^{\prime}\right)-W\left(x_{t}\right)\right) / \beta^{t}}$, where $W(x)=w^{T} x ; 0<\beta<1$ is a constant which is usually picked to be close to 1 . If $\alpha \geq 1$, then $x_{t}^{\prime}$ is accepted as $x_{t+1}$. Otherwise, it is accepted with probability $\alpha$.

This exploration starting from $P_{i}$ continues for a number of iterations, or until $x_{t}$ converges. The best solution encountered in this process is recorded. After exploring

```

        Initialize \(x_{0}\) with \(P_{i}\);
        for \(t=1,2, \ldots, n\) do
            Reduce \(x_{t}\) to \(x_{t}^{\prime}\) probabilistically by removing a proportion \(q\) of
                vertices with relatively lower \(W D\) values;
            repeat
                    Identify candidate vertices compatible with current \(x_{t}^{\prime}\);
                Calculate \(W D^{\prime}\) for each candidate;
                Update \(x_{t}^{\prime}\) by adding the candidate with the largest \(W D^{\prime}\);
            until \(x_{t}^{\prime}\) cannot be further improved;
            Calculate \(\alpha=\min \left[1, e^{\left(W\left(x_{t}^{\prime}\right)-W\left(x_{t}\right)\right) / \beta^{t}}\right]\);
            Update \(x_{t+1}\) as \(x_{t}^{\prime}\) with probability \(\alpha\), otherwise \(x_{t+1}=x_{t}\);
        end
    end
    return the best solution found in the process;
```

the neighborhood for all the known MISs, the best solution is returned. A formal description can be found in Algorithm 1.

Our algorithm is essentially a variant of simulated annealing method Kirkpatrick et al. (1983), since the maximization of $W(x)=w^{T} x$ is equivalent to the minimization of the energy function $E(x)=-W(x)=-w^{T} x$. Lines 5 to 10 in Alg. 1 define a randomized "moving" procedure of making a transition from $x_{t}$ to its neighbor $x_{t}^{\prime}$. When calculating the acceptance ratio $\alpha=e^{\left(W\left(x_{t}^{\prime}\right)-W\left(x_{t}\right)\right) / \beta^{t}}$, suppose $T_{0}=1$ (initial temperature), then it is equivalent to $\alpha=e^{\left(-\left(W\left(x_{t}\right)-W\left(x_{t}^{\prime}\right)\right)\right) /\left(\beta^{t}\right)}=e^{\left(-\left(E\left(x_{t}^{\prime}\right)-E\left(x_{t}\right)\right)\right) /\left(\beta^{t}\right)}$. Hence Algorithm 1 is a variant of simulated annealing. Therefore, our algorithm converges in theory.

In practice, the convergence of our algorithm is fast. In all the experiments presented in next section, our algorithm converges in less than 100 iterations. The reason is that our algorithm takes advantage of that the known MISs are close to distinct
local maximum. Also, the local search heuristic of our algorithm is effective to find better candidate in the neighborhood.

The parameter $q$ controls the "radius" of the neighborhood to be explored in each iteration. Small $q$ means small "radius" and results in more iterations to converge. On the other side, using large $q$ will take less advantage of the known MISs. Unstable exploration also results in more iterations to converge.

Since our algorithm explores the neighborhood of each known MIS independently, its efficiency can be further improved by using parallel computation.

### 3.3 Experimental Evaluation

We evaluate the performance of our approach to clustering aggregation and SAMIS algorithm for MWIS problem with three experiments.

In these experiments, for the underlying clustering algorithms, including K-means, single linkage, complete linkage and Ward's clustering, we use the implementations in MATLAB. Unless specified explicitly, the parameters are MATLAB's defaults. For example, when using K-means, we only specify the number $K$ of desired clusters. The default "Squared Euclidean distance" is used as the distance measure. When calculating silhouette coefficients, we use MATLAB's function "silhouette(X,clust)" and the default metric "Squared Euclidean distance". For robustness in our experiments, we tolerate slight overlap between clusters. That is, for the adjacency matrix $A=\left(a_{i j}\right)_{n \times n}, a_{i j}=1$ if $\frac{\left|c_{i} \cap c_{j}\right|}{\min \left(\left|c_{i}\right|,\left|c_{j}\right|\right)}>0.05$, and $a_{i j}=0$ otherwise. In these experiments, the parameters of our local search algorithm are: $q=0.3 ; \beta=0.999$; iteration number $n=100$. We test different combinations of $q=0.1: 0.1: 0.5$ and $n=100: 100: 1000$. The results are almost the same.

In the first experiment, we evaluate our approach's ability to achieve good performance without specifying the optimal input parameters for the underlying clustering algorithms. We use the data set from Fränti \& Virmajoki (2006). This data set con-

Figure 3.1:
Clustering aggregation without parameter tuning. (top row) Original data. (bottom row) Clustering results of our approach. Best viewed in color.
sists of 4 subsets (S1, S2, S3, S4) of synthetic 2-d data points. Each subset contains 5000 vectors in 15 Gaussian clusters, but with different degree of cluster overlapping. We choose K-means as the underlying clustering algorithm and vary the parameter $K=5: 1: 25$, which is the desired number of clusters. Since different runs of K-means starting from random initialization of centroids typically produce different clustering results, we run K-means 5 times for each value of $K$. That is, there are a total of $21 \times 5=105$ different input clusterings. Note that, in order to show the performance of our approach clearly, we do not perform the post-processing of assigning the missing data points to their nearest clusters.

As shown in Fig. 3.1, on each of the four subsets, the aggregated clustering obtained by our approach has the correct number (15) of clusters and near-perfect

Figure 3.2:
Clustering aggregation on four different input clusterings. Best viewed in color.
structure. Only a very small portion of data points is not assigned to any cluster. These results confirm that our approach can automatically decide the optimal number of clusters without any parameter tuning for the underlying clustering algorithms.

In the second experiment, we evaluate our approach's ability of combining the advantages of different underlying clustering algorithms and canceling out the errors introduced by them. The data set is from Gionis et al. (2007). As shown in the fifth panel of Fig. 3.2, this synthetic data set consists of 7 distinct groups of 2d data points, which have significantly different shapes and sizes. There are also some "bridges" between different groups of data points. Consequently, this data set is very challenging for any single clustering algorithm. In this experiment, we
use four different underlying clustering algorithms implemented in MATLAB: single linkage, complete linkage, Ward's clustering and K-means. The first two are both agglomerative bottom-up algorithms. The only difference between them is that when merging pairs of clusters, single linkage is based on the minimum distance, while complete linkage is based on maximum distance. The third one, Ward's clustering algorithm, is also an agglomerative bottom-up algorithm. In each merging step, it chooses the pair of clusters which minimize the sum of the square of distances from each point to the mean of the two clusters. The fourth algorithm is K-means.

For each of the underlying clustering algorithms, we vary the input parameter of desired number of clusters as $4: 1: 10$. That is, we have a total of $7 \times 4=28$ input clusterings.

Note that, unlike Gionis et al. (2007), we do not use the average linkage clustering algorithm, because by specifying the correct number of clusters, it can generate nearperfect clustering by itself. We abandon the best algorithm here in order to show the performance of our approach clearly. But, in practice, by utilizing good underlying clustering algorithms, it can significantly increase the chance for our approach to obtain superior aggregated clusterings. Like the first experiment, we do not perform the post-processing in this experiment.

In the first four panels of Fig. 3.2, we show the clustering results obtained by the four underlying clustering algorithms with the number of clusters set to be 7 . Obviously, even with the optimal input parameters, the results of these algorithms are far from being correct. The ground truth and the result of our approach are shown in the fifth and sixth panels, respectively. As we can see, our aggregated clustering is almost perfect, except for the three green data points in the "bridge" between the cyan and green "balls". These results confirm that our approach can effectively combine the advantages of different clustering algorithms and cancel out the errors introduced by them. Also, in contrast to the other consensus clustering algorithms,

such as Gionis et al. (2007), our aggregated clustering is obtained without specifying the optimal input parameters for any of the underlying clustering algorithm. This is a very desirable feature in practice.

The third experiment is performed on 7 real data sets from the UCI machine learning repository Lichman $(\overline{2013})$, including Iris, Zoo, Semeion Handwritten Digit (Semeion), Pen Digits (PD), Vowel, ISOLET and Letter Image Recognition (Letter). The detailed information of these data sets are given in Table 3.1. For instance, Iris has 150 data objects; each of them has 4 attributes; and the data objects are from 3 classes.

To generate multiple base clusterings for each data set, we use two classic clustering algorithms, k -means and complete-linkage, and vary the desired cluster number $k$ in the range shown in Table 3.2 . For instance, on Iris data set, we vary $k$ from 2 to 10 with a step size of 1 for both k -means and complete-linkage algorithms. As a result, we obtain 18 base clusterings with a total of 108 clusters.

Then a simple undirected and vertex-weighted graph is constructed. Each vertex

represents a cluster. If two clusters $c_{i}$ and $c_{j}$, which are from two different clusterings, contain some common data objects, we say they are overlapping. For any two overlapping clusters, there is an edge connecting the vertices representing them. The basic statistics of the derived graph of each data set are given in Table 3.2. Note that since k-means may return different clusterings for the same data set and the same $k$ due to its randomness in initialization, we construct 100 graphs for each data set and report the average edge number and average vertex degree. The weight of each vertex is defined as sum of the silhouette coefficients of the data objects belonging to the corresponding cluster.

We first compare our SAMIS algorithm with state-of-the-art maximum-weight clique solvers, which are applied on the complementary graphs. In consideration of the randomness of k-means, we generate 10 graphs for each data set and report the average performance. The algorithms for comparison include FastWClq, LSCC, LSCC + BMS, RRWL and MWBC, which serves as the baseline and just returns the set of vertices belonging to the same base clustering and having the maximum sum of weights. For LSCC, the search depth $L$ was set to 4,000 . When employing the BMS heuristic, the parameter $k$ was set to 100, as in Y. Wang et al. (2016). For FastWClq, the parameters $k_{0}$ and $k_{\max }$ for the dynamic BMS heuristic were set to 4 and 64 respectively, as in Cai \& Lin (2016). For RRWL, we set the cut off to be 10 minutes and use one seed. FastWClq, LSCC, LSCC+BMS and RRWL are implemented in C++ and invoked from MATLAB.

As shown in Table 3.3, the performance of SAMIS is very close to those of state-of-the-art.

Then we evaluate the performance of our clustering aggregation approach CA+SAMIS. The comparison algorithms include COMUSA Mimaroglu \& Erdil (2011), WEAC+SL D. Huang et al. (2015), WEAC+CL D. Huang et al. (2015), WEAC+AL D. Huang et al. (2015), GP-MGLA D. Huang et al. (2015), ECFG D. Huang et al. (2016a), PTA+SL D. Huang et al. (2016b), PTA+CL D. Huang et al. (2016b), PTA+AL D. Huang et al. (2016b) and PTGP D. Huang et al. (2016b). For these algorithms, we follow the author-recommended or default settings and parameters.

Note that COMUSA, ECFG and our CA+SAMIS can automatically determine the cluster number in the aggregated clustering, while the rest algorithms need it as an input parameter. For fair comparisons, we follow the experimental protocol in D. Huang et al. (2016a) and specify the cluster number for those "non-automatic" algorithms to be the one automatically estimated by CA+SAMIS. For CA+SAMIS, there may be a couple of data objects which are not covered by the aggregated clustering or are covered by more than one cluster due to the slight overlap. In that case, we perform the post-processing to assign such data objects to their nearest clusters.

The quality of the final aggregated clustering is measured in terms of the normalized mutual information (NMI) Strehl \& Ghosh (2002b). A higher NMI indicates that the aggregated clustering matches the ground-truth class memberships better. In consideration of the randomness of k -means, we run experiment on each data set 100 times and report the average NMI.

As shown in Table 3.4, CA+SAMIS is very competitive in clustering aggregation compared with other state-of-the-art techniques.

Table 3.4: Average Performance of Clustering Aggregation in Terms of NMI

| Method | Iris | Zoo | Semeion | PD | Vowel | ISOLET | Letter |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

### 3.4 Conclusion

We formulate clustering aggregation as a special instance of maximum-weight independent set problem and propose a novel local search algorithm for solving it. Experimental results on many real-world data sets demonstrate that both our algorithm for the maximum-weight independent set problem and our approach to clustering aggregation achieve good performance.
